      record="Revision/kohn_sham/results/exx/exact-fock-variant.csv, "
             "E_exact_fock_scf")
```

The record of the exact-Fock variant, its 20 rows with $N = 8$, and the check that their self-consistent energies are all below 10^{-12} in size: zero up to rounding, as Section 14.27 predicts. Out [12] shows three PASS lines.

In [13], figure 4.

```
fig, (left, right) = plt.subplots(1, 2, figsize=(10.5, 4.0))
fig.subplots_adjust(wspace=0.32)  # room for the label of the right panel
left.semilogy(y, n_y, label="proper density $n(y) = 4Pa^2$")
left.semilogy(y, np.exp(6.0 * y) * n_y, "--",
              label="coordinate density $e^{6Hy} n(y)$")
left.set_xlabel("$y$ (units of $1/H$; tip at $-3$, brane at $0$)")
left.set_ylabel("density (logarithmic)")
left.set_title("the eight zero modes ($N = 8$, $\\lambda = 0$)")
left.legend(fontsize=8)
```

Left panel, logarithmic: the proper density and the coordinate density $e^{6Hy}n$ (the number of particles per unit y and per unit coordinate volume of the other directions).

```
right.plot(y, -lambda_1 * n_y / 16.0, label=f"$v_v$, $\\lambda_1 = {lambda_1}$")
right.plot(y, -lambda_2 * n_y / 16.0, label=f"$v_v$, $\\lambda_2 = {lambda_2}$")
right.plot(y, np.zeros_like(y), ":", color="black",
           label="exact Fock: $v_v + w_Q = 0$")
right.set_xlabel("$y$ (units of $1/H$)")
right.set_ylabel("first-order potential (units of $m$)")
right.set_title("the Kohn-Sham potential of the zero modes")
right.legend(fontsize=8, loc="lower right")
save_figure(fig, "zero_mode_state",
            "The state of the eight brane zero modes ($N = 8$, $m = H = 1$, "
            ...)
```

Right panel: the first-order potential $v_v = -\lambda n/16$ for the two couplings and the zero exact-Fock potential. **What figure 14d.4 shows.** Left: two straight lines on the logarithmic axis. The coordinate density (dashed) rises like e^{2y} toward the brane, from about 10^{-6} to 5×10^{-4}: the particles sit at the brane. The proper density (solid) falls like e^{-4y} from 82 at the tip to 5×10^{-4} at the brane, where the two meet ($e^{6Hy} = 1$ there): per unit proper volume the gas is densest at the tip, because the proper 7-volume is tiny there. Right: the potential is zero over most of the interval and dips to -0.1 and $-0.3\,m$ only near the tip; the exact-Fock potential is zero everywhere.

In [14], the last check.

```
figure_names = ["14d_1_pair_average.png", "14d_2_energy_densities.png",
                "14d_3_exact_fock_ratio.png", "14d_4_zero_mode_state.png"]
check(all(output_file(f"{FIGURE_FOLDER}/{name}").is_file() for name in figure_names),
      "all four figure files of this notebook exist")
all_checks_passed()
```

The four figure files must exist; the last line prints ALL 16 CHECKS PASSED (notebook 14d). The 16 checks are: 1 in In [2], 1 in In [3], 3 in In [4], 1 in In [6], 2 in In [7], 3 in In [8], 1 in In [10], 3 in In [12] and 1 in In [14].

14.32 What we proved, what we computed, what we assumed

PROVED (exact; the derivation is in this chapter, and the Revision record checks it in `Revision /kohn_sham/reports/ks-theory-python.json`, with the checks marked "both" also in `Revision /kohn_sham/reports/ks-theory-wolfram.json`):

statement (section; notebook)	**record checks**
the hidden coordinate, the warped form, the volume factor e^{6Hy} without a_4 (Section 14.2; Notebook 14a)	`geometry_hidden_coordinate` and `geometry_sqrt_det` (both), `geometry_warped_form`
$\gamma^\mu \Omega_\mu = 3H\gamma^{(x_0)}$ along every history; the pieces of the inflating and the deflating directions cancel (Section 14.4; Notebook 14a)	`spin_connection_compatibility`, `spin_connection_slash_3H`, `spin_connection_time_terms_cancel` (both), `spin_connection_time_term_value`
the factor W^{-3} removes the spin connection; the Hamiltonian is Hermitian (Section 14.4; Notebook 14a)	`ansatz_removes_spin_connection`, `ansatz_without_W3_term_survives`, `hamiltonian_16_hermitian` (both)
eight blocks of two components, two block types, the block forms and the block Hamiltonian (Section 14.5; Notebook 14a)	`blocks_commuting_set`, `blocks_basis_unitary`, `blocks_forms`, `block_hamiltonian`, `block_ode_equivalent`, `block_type_relation` (both), `blocks_projectors`, `blocks_not_everything_block_diagonal`
the chirality matrix Γ pairs the block types and reverses the mass (Section 14.6; Notebook 14a)	`blocks_relation_to_Gamma`, `block_Gamma_map` (both)
the levels depend only on the length of the 3-momentum (Section 14.6; Notebook 14a)	`rotation_invariance` (both)
the exact rescaling identity between the slices (Section 14.7; Notebooks 14a and 14c)	`rescaling_identity` (both)
the real form, the boundary term, the mirror map and the parities, the tip family, the constant current, the suppression at the tip (Section 14.12; Notebook 14b)	`bc_mirror_map_PA`, `bc_mirror_parities_of_densities`, `bc_brane_parity_conditions`, `bc_self_adjoint_boundary_term`, `bc_tip_family`, `bc_current_conserved_along_y`, `bc_tip_asymptotics` (all both)
the exact free levels at zero 3-momentum, the zero mode and the gap (Section 14.13; Notebook 14b)	`bc_exact_k0_spectra` (both)

statement (section; notebook)	record checks
the equation of the Pruefer angle; the shooting function grows with the energy; one level per label (Section 14.14; Notebook 14b)	derived in Section 14.14 (not a separate check of the record); Notebook 14b checks the equation of the angle with sympy and the labels numerically
the slope of the brane band; the band is odd in k (Section 14.19; Notebook 14c)	`brane_band_slope` (both)
$h_{\mathbf{p}}^2 = E^2$; $\rho = (nB + SC)/16$; Wick's rule; the exact local exchange; the ratio $-1/8$ (Section 14.26; Notebook 14d)	`gas_mode_projector`, `gas_angular_average`, `gas_densities`, `exchange_uniform_gas` (both), `gas_negative_energy_modes`, `hf_wick_contraction`, `filled_shell_ratio`
the Kohn-Sham potentials; the Lagrangian on shell (Section 14.27; Notebook 14d)	`ks_potentials`, `ks_onshell_lagrangian` (both)
the exact Fock exchange of the closed-shell states and the term $+\frac{\lambda}{32}Q^2$ that the functional omits (Section 14.27; Notebook 14d)	`exchange_slab_exact_fock` (both)

COMPUTED (numerical, with the record that holds the numbers and their measured accuracy):

result (notebook)	record and measured accuracy
the 54 free levels at $k = 0$ by RK4 shooting (Notebook 14b)	`Revision/kohn_sham/results/spectrum/free-k0-analytic.csv`; check `free_k0_analytic_spectra` of `Revision/kohn_sham/reports/ks-rust-solver.json`; measured largest errors against the exact levels 7.23×10^{-10} below $4m$ and 5.05×10^{-8} above (tolerances of the record 5×10^{-9} and 3×10^{-7}); the notebook reproduces both numbers and agrees with the Rust levels to 7.1×10^{-15}
fourth-order convergence (Notebook 14b)	check `refined_free_spectra_convergence_order` of `Revision/kohn_sham/reports/ks-rust-determinism.json`; measured: median error ratio 16.00 over 39 levels, largest errors 5.050×10^{-8} (canonical step) and 3.157×10^{-9} (refined step), reproduced by the notebook
the brane band and three other levels for k from 0 to 4 (Notebook 14c)	`Revision/kohn_sham/results/spectrum/brane-band.csv`; accuracy: reproduced to 10^{-11}
the numerical slope $c\,e^{-\alpha_{4,0}}$ at five slices (Notebook 14c)	`brane-band-slope.csv` (spectrum folder); check `free_brane_band_slope`; accuracy: 1.87×10^{-12} relative
the rescaling identity solved as two separate problems (Notebook 14a, the partner parameters)	`Revision/kohn_sham/results/rescaling/rescaling.csv`; checks `rescaling_identity_between_slices` and `rescaling_identity_energy_profiles`; accuracy: levels to 1.5×10^{-13}, energies and profiles to 3.3×10^{-13}

result (notebook)	record and measured accuracy
the gap of the free $N = 8$ state, 0.4307 to $0.0642\,m$ along the history (Notebook 14c)	`closed-shells.csv` (spectrum folder); accuracy: reproduced to 10^{-11}
at the cutoff $L = 3$ and the slice 0 the band does not feel the tip angle for $k \neq 0$ (Notebook 14c; the later slices are not computed)	`tip-angle.csv` (spectrum folder); check `free_tip_angle_insensitivity`; accuracy: shifts below the suppression factor
the dependence on the cutoff L from 3 to 6 (Section 14.20; the Revision record, not repeated by a notebook of this chapter)	`Revision/kohn_sham/tip_convergence/` (README and `tip-convergence-table.csv`); report `tip-convergence.json`, 7 of 7 checks PASS; the step error of every run at most 5×10^{-9}; the free results with $k \neq 0$ at $L = 3$ low by up to 1.4% (E_{KS}) and 12% (the p_0 integral) at $a_{4,0} = 2$; the interacting $N = 8$ energy at $L = 3$ about one third of its large-L value
the particle labels, the closed shells, the bulk edge and $N = 8, 136, 688$ (Notebook 14c)	check `free_particle_branch_labels`; `closed-shells.csv`; `Revision/kohn_sham/results/parameters.json`; accuracy: exact agreement of the shells; energies to 10^{-11}
the state $N = 8$: $n_{\max} = 82.2208638894$, $\lambda_1 = 0.01946$, $\lambda_2 = 0.05838$, exact-Fock energy 0 (Notebook 14d)	`Revision/kohn_sham/results/ground/summary.csv`; `parameters.json`; `Revision/kohn_sham/results/exx/exact-fock-variant.csv`; accuracy: 10^{-9} relative; energies below 10^{-12}

ASSUMED (starting points that this chapter does not derive):

- The good sector: the orbitals do not depend on the extra times x_5, x_6, x_7 (Section 14.3; Chapters 8 and 10 give the reasons).
- The Z2 mirror brane at $y = 0$, with its two parities; with it the weight $w = \frac{1}{2}$ of the densities and the mirror copy with the mass $-m$ (Section 14.12).
- The regular tip condition at the cutoff $y = -L$, $L = 3$: a choice of the numerical model. At this cutoff and the slice $a_{4,0} = 0$, where it was measured, its angle θ is harmless for the brane band at every lattice momentum $k \neq 0$ (for the other levels with $k \neq 0$ only the estimate of Section 14.12 applies; at the later slices, where the suppression factor of Section 14.12 is no longer small for the lowest lattice momenta, this is not computed), and it is decisive for the zero modes at $k = 0$ (Section 14.20). The cutoff L itself matters, as the Revision record measured for $L = 3$ to 6 (Section 14.20; `Revision/kohn_sham/tip_convergence/`): the free results with $k \neq 0$ converge, but the recorded $L = 3$ values are low by up to 1.4% in E_{KS} and 12% in the p_0 integral at $a_{4,0} = 2$ (the redshifted brane band reaches the tip); the nonzero $k = 0$ levels approach $\pm m$ only algebraically, so the bulk edge and $N = 688$ are $L = 3$ choices; the interaction energy of the brane zero modes depends strongly on L, and the couplings are calibrated at $L = 3$.
- The deflating history $a_4 = AHx_4$ with $A = 1$ is a **prescribed background**: the Kohn-Sham states are computed on it but are not its source in the field equations of a_4 (`Revision/field_e`

quations_a4/reports/ks-source-conditions.json; Chapter 17). The Kohn-Sham gas is a test field.

- The stationary-slice (adiabatic) ansatz: at each slice the instantaneous Kohn-Sham states are computed (Section 14.3); whether the gas can follow the history is measured in Chapter 15.
- The convention that counts the zero modes at $k = 0$ as particle levels (Section 14.21).
- The functional: Hartree plus the uniform-gas exchange, without correlation (an approximation; the exact Fock exchange differs by $+\frac{\lambda}{32}Q^2$ and is reported as a diagnostic, Section 14.27).
- The canonical numbers $H = m = 1$, $L = 3$, $\Delta k = 0.25$, $v_t = 1$ and the five slices.

HYPOTHESIS: none in this chapter.

OPEN: the justification of the zero-mode convention; the effect of the tip angle θ on the levels with $k \neq 0$ at the later slices, which neither the record nor a notebook computes (Section 14.20); the time-dependent (non-adiabatic) evolution of the gas along the history; the action of the gas back on a_4 (the history is not a solution of the coupled equations); the correlation energy of the contact interaction in this geometry; the limit $L \to \infty$ of the cutoff where the Revision record does not establish it (the state $N = 688$ at $a_{4,0} = 0$, and 7 of the 19 interacting states studied, whose self-consistent iteration fails before their energies meet the record's convergence rule; Section 14.20).

Honesty about pairs and charges (rule of Chapter 0). Two places of this chapter touch the pairing of universes. The chirality matrix Γ maps every solution with the mass M onto a solution with the mass $-M$ (Section 14.6), and the ASSUMED mirror brane pairs the patch, with $+m$, with a mirror copy carrying $-m$ (Section 14.12). Both are exact maps between sets of solutions; Chapters 18 and 19 prove the theorems T1 and T3 built on them. Neither says that a universe, or a pair of universes, is created: no creation process, rate or amplitude follows from these equations (Chapter 20 gives the complete list of what is and is not proved). The words particle and sea in Section 14.21 describe the filling of the levels of the normal-ordered quantum field; this chapter makes no statement about matter and antimatter, which Chapter 21 treats, and it does not claim that the theory explains why our universe contains more matter than antimatter.

14.33 Exercises

Exercise 14.1. (a) Show that in the coordinate y the volume factor is $\sqrt{|g|} = e^{6Hy}$, and compute it at $y = -3$ for $H = 1$. (b) Compute the momentum weight κ at the cutoff $y = -3$ and at the brane $y = 0$, for the slices $a_{4,0} = 0$ and 2 ($H = 1$). (c) A density per unit y and per unit coordinate volume is turned into a proper density by dividing it by $\sqrt{|g|}$. Explain with (a) why the proper density of the zero modes is largest at the cutoff, although the orbitals sit at the brane.

Answer 14.1. (a) The scale factors are $e^{a_4}W$ (three times), 1, $e^{-a_4}W$ (three times) and 1, with $W = e^{Hy}$ (Section 14.2). The square root of the absolute value of the determinant of a diagonal metric is the product of the scale factors: $(e^{a_4}W)^3(e^{-a_4}W)^3 = e^{3a_4-3a_4}W^6 = e^{6Hy}$. At $y = -3$: $e^{-18} \approx 1.52 \times 10^{-8}$. (b) $\kappa = e^{-Hy-a_{4,0}}$. At $y = -3$: $e^{3-a_{4,0}}$, which is $e^3 \approx 20.09$ at the slice 0 and $e^1 \approx 2.718$ at the slice 2. At $y = 0$: $e^{-a_{4,0}}$, which is 1 and $e^{-2} \approx 0.135$. (c) The zero-mode orbital gives the coordinate density $\propto a^2 \propto e^{2My}$, largest at the brane. Dividing by e^{6Hy} gives $e^{(2M-6H)y}$, which for $M = H = 1$ is e^{-4y}: it grows toward the tip. The proper 7-volume near the tip is so small (the factor e^{-18} at the cutoff) that the few particles there are packed densely (Figure 14d.4).

Exercise 14.2. Using the two rules of Section 14.5, show that $A_0A_1A_4 = -J$, and deduce from it the block form $A_4 \to j\sigma_1$. Then derive the block form of $\gamma^{(x_4)} = A_0A_4$.

Answer 14.2. $A_0A_1A_4 = \gamma^{(x_0)}\gamma^{(x_0)}\gamma^{(x_1)}\gamma^{(x_0)}\gamma^{(x_4)}$. The first two factors give $(\gamma^{(x_0)})^2 = \eta_{00} = 1$, so the product is $\gamma^{(x_1)}\gamma^{(x_0)}\gamma^{(x_4)}$. Exchanging the first two factors (they anticommute) gives $-\gamma^{(x_0)}\gamma^{(x_1)}\gamma^{(x_4)} = -J$. In a block of type j, J is the number j, so $A_0A_1A_4 = -j$ there. With $A_0 \to \sigma_3$ and $A_1 \to -i\sigma_2$: $\sigma_3(-i\sigma_2) = -i\sigma_3\sigma_2 = -i(-i\sigma_1) = -\sigma_1$, so $-\sigma_1 A_4 = -j$, and multiplying by $-\sigma_1$ from the left ($\sigma_1^2 = 1$): $A_4 = j\sigma_1$. Finally $\gamma^{(x_4)} = \gamma^{(x_0)}\gamma^{(x_0)}\gamma^{(x_4)} = A_0A_4 \to \sigma_3(j\sigma_1) = j\sigma_3\sigma_1 = ij\sigma_2$, as in Section 14.5.

Exercise 14.3. (a) Show that the column $\chi = (\cos\frac{\theta}{2},\ i\sin\frac{\theta}{2})$, that is $(a, b) = (\cos\frac{\theta}{2}, \sin\frac{\theta}{2})$ in real form, satisfies $Q(\theta)\chi = \chi$ for $Q(\theta) = \cos\theta\,\sigma_3 + \sin\theta\,\sigma_2$. (b) Show that the tip condition with $\theta = \pi$ is $a(-L) = 0$, and that the matrix σ_2 of Section 14.6 turns the canonical tip condition $b(-L) = 0$ into it.

Answer 14.3. (a) For $\chi = (a, ib)$ the products of Section 14.12 give $\sigma_3\chi = (a, -ib)$ and $\sigma_2\chi = (b, ia)$, so $Q\chi = (a\cos\theta + b\sin\theta,\ i(a\sin\theta - b\cos\theta))$. With $a = \cos\frac{\theta}{2}$, $b = \sin\frac{\theta}{2}$ the first entry is $\cos\theta\cos\frac{\theta}{2} + \sin\theta\sin\frac{\theta}{2} = \cos(\theta - \frac{\theta}{2}) = \cos\frac{\theta}{2} = a$, and the bracket of the second is $\sin\theta\cos\frac{\theta}{2} - \cos\theta\sin\frac{\theta}{2} = \sin(\theta - \frac{\theta}{2}) = \sin\frac{\theta}{2} = b$ (the subtraction formulas of cosine and sine). So $Q\chi = \chi$. (b) For $\theta = \pi$, $Q = -\sigma_3$ and $(1 - Q)\chi = (1 + \sigma_3)\chi = (2\chi_1, 0) = 0$ means $\chi_1(-L) = 0$, that is $a(-L) = 0$. The map $\chi \to \sigma_2\chi$ sends (a, ib) to (b, ia), so the new components are $\tilde{a} = b$ and $\tilde{b} = a$: the condition $b(-L) = 0$ of the old orbital becomes $\tilde{a}(-L) = 0$, the condition with $\theta = \pi$. (The Rust solver's numerical self-test of the Kohn-Sham-level map, check t3_block_map_solver_selftest of `Revision/kohn_sham/reports/ks-rust-solver.json`, solves the problem with (m, λ) and the tip $\theta = 0$ and the problem with $(-m, \lambda)$ and exactly this transformed tip, $\theta = \pi$, and finds the same levels; the record states that this self-test is not a proof of T3, which Chapter 19 proves.)

Exercise 14.4. Let p be the cubic polynomial with the values f_0, f_1 and the derivatives d_0, d_1 at the two ends of an interval of length h. Show that its value at the midpoint is $\frac{1}{2}(f_0 + f_1) + \frac{h}{8}(d_0 - d_1)$, the formula used by `orbital` in Notebooks 14b and 14c.

Answer 14.4. Measure the position from the midpoint, s, so that the ends are $s = \mp h/2$, and write $p(s) = A + Bs + Cs^2 + Ds^3$; the value at the midpoint is A. Then $p(\mp h/2) = A \mp Bh/2 + Ch^2/4 \mp Dh^3/8$ and $p'(\mp h/2) = B \mp Ch + 3Dh^2/4$. Adding the two values: $f_0 + f_1 = 2A + Ch^2/2$ (the odd terms cancel). Subtracting the two derivatives: $d_0 - d_1 = -2Ch$, so $C = (d_1 - d_0)/(2h)$. Hence $A = \frac{1}{2}(f_0 + f_1) - Ch^2/4 = \frac{1}{2}(f_0 + f_1) - \frac{h}{8}(d_1 - d_0) = \frac{1}{2}(f_0 + f_1) + \frac{h}{8}(d_0 - d_1)$.

Exercise 14.5. For $M = 1$ and $L = 2$ (the second case of Notebook 14b): (a) compute the lowest positive even level; (b) show that the lowest odd root p_0 lies between $\pi/4$ and $\pi/2$ and that no root lies between 0 and $\pi/4$; (c) the record gives the lowest odd level $1.519802561206\,m$; compute p_0 from it and check (b).

Answer 14.5. (a) $\varepsilon = \sqrt{M^2 + (\pi/L)^2} = \sqrt{1 + (\pi/2)^2} = \sqrt{1 + 2.4674} = \sqrt{3.4674} = 1.862096\,m$; the record `Revision/kohn_sham/results/spectrum/free-k0-analytic.csv` lists 1.862095889118587 (column eps_analytic, $m = 1$, $L = 2$, even, label 1). (b) With $f(p) = \sin(2p) + p\cos(2p)$: $f(\pi/4) = \sin(\pi/2) + \frac{\pi}{4}\cos(\pi/2) = 1 > 0$ and $f(\pi/2) = \sin\pi + \frac{\pi}{2}\cos\pi = -\pi/2 < 0$, so a root lies between them (Step 4 of Section 14.13); for $0 < p < \pi/4$ both $\sin(2p)$ and $\cos(2p)$ are positive, so $f(p) > 0$ and there is no root. (c) $p_0 = \sqrt{\varepsilon^2 - M^2} = \sqrt{1.519803^2 - 1} = \sqrt{2.309801 - 1} = \sqrt{1.309801} = 1.14447$, and indeed $\pi/4 = 0.785 < 1.144 < 1.571 = \pi/2$.

Exercise 14.6. (a) Show that for $M = H = 1$ the slope of the brane band is $c = 2e^{-a_{4,0}}/(1 + e^{-L})$.

(b) Evaluate it at the slice 0 for $L = 2$ and $L = 4$ and compare with Notebook 14c, Out [5]. (c) Evaluate it for $L = 3$ at the slice 1. (d) What is the limit for $L \to \infty$, and why is it not 1, the value of κ at the brane at the slice 0?

Answer 14.6. (a) Section 14.19 with $M = H = 1$: $c = e^{-a_{4,0}} \cdot \frac{2}{1} \cdot (1 - e^{-L})/(1 - e^{-2L})$, and $1 - e^{-2L} = (1 - e^{-L})(1 + e^{-L})$, so the factor $1 - e^{-L}$ cancels. (b) $L = 2$: $2/(1 + e^{-2}) = 2/1.135335 = 1.761594$; $L = 4$: $2/(1 + e^{-4}) = 2/1.018316 = 1.964028$; both equal the printed numerical and exact values. (c) $2e^{-1}/(1 + e^{-3}) = 1.905148 \times 0.367879 = 0.700865$, the value of Out [5] for the slice 1 (0.700864874900). (d) For $L \to \infty$, $e^{-L} \to 0$ and $c \to 2$. The slope is the average of $\kappa = e^{-y}$ over the zero mode, whose weight $2e^{2y}$ extends toward the tip; the average of e^{-y} with the weight $2e^{2y}$ over $(-\infty, 0]$ is $\int 2e^{y} dy = 2$, larger than the value 1 at the brane.

Exercise 14.7. Estimate the gap of the free $N = 8$ state at the slices 0 and 1 from the first-order band, $\varepsilon \approx c\, e^{-a_{4,0}} k$ with $k = 0.25$, and compare with the computed gaps of Section 14.20. Why is the estimate too large, and why is it better at the later slice?

Answer 14.7. Slice 0: $1.905148 \times 0.25 = 0.4763\, m$ against the computed $0.4307\, m$, too large by $0.0456\, m$ (about 11 per cent). Slice 1: $0.700865 \times 0.25 = 0.1752\, m$ against $0.1703\, m$, too large by $0.0049\, m$ (about 3 per cent). The band bends below its tangent line ck (Figure 14c.1), so the straight line overestimates it. By the rescaling identity the gap at the slice 1 is the band at the slice 0 at the smaller momentum $0.25e^{-1} = 0.092$, where the band is still close to its tangent: along the history the redshift moves the lattice momenta into the region where the first-order formula is accurate.

Exercise 14.8. For a single momentum at rest, $\mathbf{p} = 0$, show that the projector on the eight positive-energy modes is $G_0 = \frac{1}{2}(1 - i\gamma^{(x_4)})$, that these eight modes, filled, give $\rho = \frac{1}{2}(B + C)$, and deduce $n = S = 8$ and $e_x/e_H = -1/8$.

Answer 14.8. At $\mathbf{p} = 0$, $h_0 = M(-i\gamma^{(x_4)})$ and $E = M$, so $G_0 = \frac{1}{2}(1 + h_0/M) = \frac{1}{2}(1 - i\gamma^{(x_4)})$. The filled modes give $\rho = G_0 B = \frac{1}{2}(B + (-i\gamma^{(x_4)})B) = \frac{1}{2}(B + C)$, by $(-i\gamma^{(x_4)})B = C$ (Section 14.26). Then $n = \mathrm{Tr}(B\rho) = \frac{1}{2}(\mathrm{Tr}\, B^2 + \mathrm{Tr}\, BC) = \frac{1}{2}(16 + 0) = 8$ and $S = \mathrm{Tr}(C\rho) = \frac{1}{2}(\mathrm{Tr}\, CB + \mathrm{Tr}\, C^2) = 8$. With $n = S = 8$: $e_x = -\frac{\lambda}{32}(64 + 64) = -4\lambda$ and $e_H = \frac{\lambda}{2} \cdot 64 = 32\lambda$, so $e_x/e_H = -4/32 = -1/8$, the check filled_shell_ratio and Out [7] of Notebook 14d.

Exercise 14.9. Show that for any state built from orbitals with occupations $f \geq 0$ the densities at a point satisfy $S^2 + Q^2 \leq n^2$, so that the possible states fill the disk of Figure 14d.3. When does the equality hold?

Answer 14.9. For one orbital $\chi = (a, ib)$ at the point y the three contributions are $n_o = P(a^2 + b^2)$, $s_o = Pj\, 2ab$ and $q_o = P(a^2 - b^2)$ with $P > 0$ (Section 14.27), and $(2ab)^2 + (a^2 - b^2)^2 = (a^2 + b^2)^2$ (Section 14.27), so the vector (s_o, q_o) in the plane has the length n_o ($j^2 = 1$). The state has $n = \sum c_o n_o$, $(S, Q) = \sum c_o (s_o, q_o)$ with the non-negative weights $c_o = wgf$. The length of a sum of vectors is at most the sum of their lengths (the triangle inequality), so $\sqrt{S^2 + Q^2} \leq \sum c_o n_o = n$. The equality holds when all the vectors (s_o, q_o) with $c_o > 0$ point in the same direction, for example when only one kind of orbital is filled, as for the eight zero modes, where every vector is $(0, n_o)$ and the state sits at $S = 0$, $Q = n$.

Exercise 14.10. For the eight zero modes with $M = H = 1$, $L = 3$, $\ell = 8\pi$ and $v_t = 1$: (a) compute the largest proper density $n_{\max} = n(-3)$ from $n = 4Pa^2$; (b) compute the couplings λ_1 and λ_2 by the calibration rule of Section 14.27; (c) explain why the exact-Fock energy of this state is zero for every λ, while the uniform-gas exchange is not.

Answer 14.10. (a) $a^2 = \frac{2}{1-e^{-6}}e^{2y}$ and $P = e^{-6y}/(8\pi)^3$, so $n(-3) = 4 \cdot \frac{2}{1-e^{-6}} \cdot e^{-6} \cdot e^{18}/(8\pi)^3 = \frac{8e^{12}}{(1-e^{-6})(8\pi)^3}$. With $e^{12} = 162754.79$, $1 - e^{-6} = 0.997521$ and $(8\pi)^3 = 15875.21$: $n_{\max} = 1302038.3/(0.997521 \times 15875.21) = 82.2209$, the RESULT of Notebook 14d (82.2208638894) and the record. (b) The strength is $n_{\max}/16 = 5.13880$ ($S = 0$, so only $|n|/16$ counts); $0.1/5.13880 = 0.019460$ and $0.3/5.13880 = 0.058380$, rounded to four significant digits $\lambda_1 = 0.01946$, $\lambda_2 = 0.05838$. (c) The state has $S = 0$ and $Q = n$ at every point. The exact Fock exchange $-\frac{\lambda}{32}(n^2 + S^2 - Q^2)$ is therefore zero, and the exact-Fock potential acting on the orbitals $(a, 0)$ is $v_v + w_Q = \frac{\lambda}{16}(Q - n) = 0$: the orbitals are unchanged and their levels stay 0. The Kohn-Sham energy of the record is the sum of the filled levels minus the interaction energy integrated over the doubled patch, $E_{\mathrm{KS}} = \sum gf\varepsilon - 2\ell^3 v_t \int_{-L}^{0} e^{6Hy} e_{\mathrm{int}}\, dy$ (the second term removes the interaction that the levels count twice, as in Chapter 13; `Revision/kohn_sham/ks-theory.json`, thermodynamics.energy). Here both terms vanish: the levels are 0, and $e_{\mathrm{int}}^{\mathrm{exact}} = \frac{15}{32}\lambda S^2 - \frac{1}{32}\lambda(n^2 - Q^2) = 0$. So the energy is 0. The uniform-gas exchange $-\frac{\lambda}{32}(n^2 + S^2) = -\frac{\lambda}{32}n^2$ is not zero: it misses the $+\frac{\lambda}{32}Q^2 = +\frac{\lambda}{32}n^2$ that cancels it.

15 Solving the Kohn-Sham equations along the deflating history

Chapter 14 turned the Kohn-Sham problem of the field dirac16complex in the author's primordial universe into a problem a computer can solve: pairs of real functions of one variable, the hidden coordinate y, in eight independent blocks, with an effective mass and a potential made by the quanta themselves. This chapter solves that problem. It explains, line by line, the numerical method of the Revision Kohn-Sham solver (a Rust program of the repository), runs the solver over its whole list of states, and reads from the results what happens to the gas of quanta while the three extra times x_5, x_6, x_7 deflate exponentially and ordinary 3-space inflates: its levels, gaps, energies, densities, its energy-momentum tensor, how well it can follow the moving background, and its thermodynamics. Five complete notebooks, 15a to 15e, repeat every step and reproduce the numbers of the Revision record.

15.1 What this chapter does

Why solving is a chapter of its own. The Kohn-Sham equations of Chapter 14 are not solved by writing down a formula. Their orbitals make the potentials and the potentials make the orbitals, so the equations must be solved again and again until the two agree (self-consistency). Each orbital is itself the solution of a boundary-value problem: a pair of differential equations with one condition at each end of the hidden direction, which has solutions only for special energies, the levels. The gas has hundreds of occupied orbitals, and the whole computation must be repeated for three particle numbers, five couplings, five instants of the deflating history and three temperatures. A method is needed that finds every level without missing one, that labels each level so that it can be followed from one iteration, coupling or instant to the next, and that is accurate enough that two independent programs agree to many digits. This chapter teaches that method and what it finds.

What is done, in order.

- The equations the solver must solve, the parameters of the model and the list of states it computes, called the **canonical matrix** (Section 15.2).

- How one level is found: shooting from the tip to the brane, the Pruefer angle that turns the search for levels into counting, and Newton's method inside a bracket (Section 15.3).
- How the levels of the whole gas are organised: shells of 3-momenta, sectors, label sets, the brane band and its redshift along the history (Section 15.4).
- Self-consistency: the loop, Anderson mixing, the energy of the gas, an exact symmetry of the smallest state, and the first excited state (Section 15.5).
- Notebook 15e, which writes the whole method in plain Python and reproduces numbers of the solver (Sections 15.6 to 15.9).
- The Rust solver and its canonical matrix, and what the matrix shows (Sections 15.10 to 15.15, Notebook 15a).
- The energy-momentum tensor of the gas, its conservation along the hidden direction, the energy change along the history, and why the gas cannot be the source of the history (Sections 15.16 to 15.20, Notebook 15b).
- Adiabaticity: whether the gas follows its instantaneous states while the background moves (Sections 15.21 to 15.25, Notebook 15c).
- Thermodynamics: the gas at a temperature, the chemical potential and why it must be computed in a special way (Sections 15.26 to 15.30, Notebook 15d).
- What we proved, what we computed, what we assumed (Section 15.31), and seven exercises with complete worked answers (Section 15.32).

The five notebooks. The run times are the two measured executions of each notebook, the build run and the check run, that section 4.5 of its provenance file `Revision/textbook/notebooks/<name>.PROVENANCE.md` records; they were measured on the computer that built the book, where the solver used 22 threads, while other programs ran at the same time, which explains the spread. A laptop may need two or three times as long, and Notebook 15a, whose solver divides its work over all cores, up to about ten minutes.

notebook	**what it computes**	**Rust, PASS lines, figures, run time**
15e	the solver's method by hand: shooting, Pruefer label, Newton, RK4 order, brane band, self-consistency for $N = 8$	no Rust; 18 PASS lines; 6 figures; 11 to 12 s
15a	the whole canonical matrix with the Rust solver, compared with the record	Rust; 25 PASS lines; 8 figures; 164 to 232 s
15b	the energy-momentum profiles, the conservation law along y, the energy change along the history	Rust; 18 PASS lines; 7 figures; 23 to 29 s

notebook	what it computes	Rust, PASS lines, figures, run time
15c	the adiabaticity measure, Hellmann-Feynman, a Fermi-level crossing	no Rust; 12 PASS lines; 6 figures; 10 to 15 s
15d	thermodynamics: chemical potential, free energy, entropy, heat capacity	Rust; 15 PASS lines; 7 figures; 36 s

The notebooks are placed in the order in which the ideas are needed: 15e first, because it teaches the method that the Rust solver uses in the others.

The status of every statement. Every statement of this chapter carries one of the five labels of Chapter 0.

- PROVED: the exact reduction to blocks, the boundary conditions as conditions on the orbitals, the exact free levels at zero momentum, the slope of the brane band, the rescaling identity between the instants of the history, the formulas of the densities, potentials, energy and energy-momentum tensor, the conservation law along y, the energy-change law along the history, the Hellmann-Feynman relation and the adiabaticity measure. They are verified twice in the Revision record, by sympy in `Revision/kohn_sham/reports/ks-theory-python.json` and by WolframScript in `Revision/kohn_sham/reports/ks-theory-wolfram.json`; the check names are given with each statement. The mathematical facts of the method (the monotone Pruefer phase, the derivative formula of the phase, the Hermite midpoint, the Anderson weights, the double counting of the interaction energy, the symmetry $E(-\lambda) = -E(\lambda)$ of the zero-mode state, the adiabaticity estimate, the heat-capacity formula and the balance form of the chemical potential) are derived line by line in this chapter.

- COMPUTED: every level, energy, density, pressure, gap, adiabaticity number and thermodynamic function. They come from the Rust solver; its own checks are in `Revision/kohn_sham/reports/ks-rust-solver.json` (42 checks, all PASS), its repeat and refined runs in `Revision/kohn_sham/reports/ks-rust-determinism.json` (14 checks, all PASS), its chemical potentials against 40-digit roots in `Revision/kohn_sham/reports/ks-rust-mermin-roots.json` (5 checks, all PASS), and the notebooks of this chapter reproduce them with the measured differences given with each number.

- ASSUMED: the good sector (no dependence on the extra times) and the Z2 mirror brane at $y = 0$. Three further assumptions are of a special kind and carry an extra word. CHOSEN: the regular tip condition at the cutoff $y = -L$ and the value $L = 3$ (the record calls them "chosen"); what the choice of L changes is COMPUTED in the record (`Revision/kohn_sham/tip_convergence/tip-convergence.json`, 7 checks, all PASS): at most 1.4 per cent of the energy of the free gas, except $N = 688$ at the first slice, but much for the interaction (Section 15.2, the paragraph on the cutoff). CONVENTION: which levels count as particles (the positive branch and the zero modes) and that the negative branch, the sea, is never populated, not even thermally; its justification is OPEN. PRESCRIBED BACKGROUND: the history $a_4 = AHx_4$ with $A = 1$; it is given, not solved for, the gas does not act back on it, and Section 15.16 shows why it cannot (the record `Revision/field_equations_a4/reports/ks-source-conditions.json`).

- HYPOTHESIS: none. No statement of this chapter goes beyond the equations and their numerical solutions.
- OPEN: the time-dependent (non-adiabatic) problem, a thermal treatment of the sea, the justification of the filling convention, and the limit of a large cutoff L wherever the record does not establish it.

What this chapter does not touch. No statement of this chapter concerns pairs of universes, their creation or matter and antimatter. One check of the solver's report, `t3_block_map_solver_selftest`, solves a state with the mass m and a state with the mass $-m$ and finds equal energies; the report itself calls it a numerical self-test of the program and NOT a proof of the theorem T3, which belongs to Chapter 19. Nothing computed here says that any universe is created, in pairs or otherwise. Where Section 15.26 speaks of thermal holes in the sea, it means excitations inside one universe, not pairs of universes.

Notation and units. The author's coordinates are $x_0, \dots, x_7$: x_1, x_2, x_3 are ordinary 3-space, which inflates with the scale factor $e^{a_4} \sin^{1/6} z$; x_4 is the time; x_5, x_6, x_7 are the three extra times, which deflate exponentially with the scale factor $e^{-a_4} \sin^{1/6} z$; x_0 is the hidden space direction, with $z = 6Hx_0$ between 0 and $\pi/2$. The hidden coordinate is $y = \ln(\sin z)/(6H)$ (Chapter 14); it runs from the **tip** $y = -L$ (where the model cuts the space) to the **brane** $y = 0$. A **slice** is one instant of the history, and $a_{4,0}$ is the value of a_4 there. In all numbers $H = 1$ and $m = 1$, so energies, momenta and temperatures are in units of m (which equals H) and lengths in units of $1/H$; Boltzmann's constant is 1, so a temperature is an energy.

15.2 The equations the solver must solve

This section collects, without proofs, the results of Chapter 14 that the solver uses, and adds the parameters of the model. Chapter 14 proves each formula; here we only need to read them.

One orbital. At a slice $a_{4,0}$, an orbital of the gas has a 3-momentum $\mathbf{k}$ (a vector of three numbers), a block type $j = +1$ or $j = -1$, and a pair of real functions $a(y)$, $b(y)$ on the interval $-L \le y \le 0$. Its level ε and the two functions obey the **block equation in real form** (`Revision/kohn_sham/ks-theory.json`, blockEquation.realForm; checks block_hamiltonian and block_ode_equivalent):

$$a' = Ma - \big(\kappa k + j(\varepsilon - v)\big)\, b, \qquad b' = \big(j(\varepsilon - v) - \kappa k\big)\, a - Mb,$$

where the prime means d/dy, $k = |\mathbf{k}|$ is the length of the momentum, $\kappa = e^{-Hy - a_{4,0}}$ is the momentum weight of Chapter 14, $M(y)$ is the **effective mass** and $v(y)$ the **potential**. The 16-component field of the orbital is built from $\chi = (a, ib)$ and the block basis of Chapter 14. The slice enters only through κ.

The boundary conditions. At the tip the solver uses the regular tip condition $b(-L) = 0$ (CHOSEN; check bc_tip_family). At the brane the ASSUMED Z2 mirror allows two kinds of orbitals, called the two **parities**: even orbitals have $b(0) = 0$, odd orbitals have $a(0) = 0$ (check bc_brane_parity_conditions). Both conditions make the current along y vanish, and with them the block Hamiltonian is self-adjoint, so the levels are real (check bc_self_adjoint_boundary_term).

The lattice of 3-momenta. 3-space is a torus of coordinate size ℓ, so the allowed momenta are $\mathbf{k} = \Delta k\,(n_1, n_2, n_3)$ with whole numbers n_1, n_2, n_3 and $\Delta k = 2\pi/\ell = 0.25$. The numbers $n_1^2 + n_2^2 + n_3^2$

are written n_2 (a single symbol, read "n-two", not the second component), and all momenta with the same n_2 form a **shell**; they have the same length $k = \Delta k\sqrt{n_2}$, and their number is written $r_3(n_2)$. For example $r_3(0) = 1$ (only the zero vector), $r_3(1) = 6$ (the six vectors $(\pm1, 0, 0)$, $(0, \pm1, 0)$, $(0, 0, \pm1)$), $r_3(2) = 12$, $r_3(3) = 8$, $r_3(4) = 6$, $r_3(7) = 0$ (no three squares add up to 7). The levels depend only on k (check rotation_invariance), and each level of block type j in the shell n_2 belongs to $4r_3(n_2)$ orbitals: the four blocks of that type times the $r_3(n_2)$ directions (ks-theory.json, blockEquation.degeneracy). This number is the **degeneracy** g of the level. A **sector** is a triple (shell n_2, block type j, parity).

Densities. The **proper** densities (per unit of proper 7-volume) of the number of quanta and of the scalar $S = \bar{\Psi}\Psi$ are sums over the levels (ks-theory.json, densities):

$$n(y) = \sum w\, g\, f\, P\, (a^2 + b^2), \qquad S(y) = \sum w\, g\, f\, P\, j\, 2ab, \qquad P = \frac{e^{-6Hy}}{\mathrm{Vol}_7},$$

where f is the occupation of the level (1 for full, 0 for empty, a number in between at a temperature), $w = \frac{1}{2}$, and $\mathrm{Vol}_7 = \ell^3 v_t$ is the coordinate volume of 3-space times the extra-time volume $v_t = 1$. With $\ell = 2\pi/\Delta k = 8\pi$, line by line:

$$\mathrm{Vol}_7 = (8\pi)^3 \cdot 1 = 512\,\pi^3 = 15875.2137.$$

Rule: $\ell^3 = 8^3\pi^3 = 512\pi^3$, and $\pi^3 = 31.00628$. The record has the same number (`Revision/kohn_sham/results/parameters.json`, physics.Vol7). The factor e^{-6Hy} turns a density per unit y into a density per unit proper volume, because the proper volume element is $\sqrt{|g|}\,dy = e^{6Hy}dy$ (Chapter 14). The weight $w = \frac{1}{2}$ belongs to the **doubled system**: the Z2 mirror makes a copy of the patch, every orbital is normalised on the patch, $\int_{-L}^{0}(a^2 + b^2)\,dy = 1$, and the particle number $N = \sum gf$ counts the quanta of the patch and of its mirror copy together; one patch holds $N/2$.

Potentials and energy. The contact interaction $U = \frac{\lambda}{2}S^2$ with the exact local exchange of Chapters 13 and 14 gives (ks-theory.json, exchange.kohnShamPotentials; check ks_potentials)

$$e_{int} = \lambda\Big(\tfrac{15}{32}S^2 - \tfrac{1}{32}n^2\Big), \qquad M = m + \frac{\partial e_{int}}{\partial S} = m + \tfrac{15}{16}\lambda S, \qquad v = \frac{\partial e_{int}}{\partial n} = -\tfrac{1}{16}\lambda n,$$

and the **Kohn-Sham energy** of the doubled system is

$$E_{KS} = \sum g\, f\, \varepsilon - 2\,\mathrm{Vol}_7 \int_{-L}^{0} e^{6Hy} e_{int}\, dy.$$

Section 15.5 derives why the interaction energy is subtracted here. The term $\frac{15}{32}\lambda S^2$ is the Hartree energy $\frac{\lambda}{2}S^2$ plus the scalar part $-\frac{1}{32}\lambda S^2$ of the exchange energy, and $-\frac{1}{32}\lambda n^2$ is the rest of the exchange energy (Chapter 13); the potential v therefore comes from the exchange alone, and the notebooks call it the exchange potential.

Which levels are particles (CONVENTION). The equations have levels of both signs. The convention of the record (ks-theory.json, thermodynamics.fillingConvention) is: particles occupy the **positive branch**, the levels whose value without interaction ($\lambda = 0$) at the same slice is positive, together with the **zero modes** at $k = 0$ (the levels $\varepsilon = 0$ of the free problem); the levels of the

negative branch form the normal-ordered **sea** and are never occupied, not even at a temperature. The justification of this convention is OPEN; Section 15.26 measures where it stops being reasonable.

The particle numbers. The record uses three particle numbers (`Revision/kohn_sham/results/parameters.json`, particleNumbers). $N = 8$ fills exactly the eight zero modes at $k = 0$ (four blocks of each type). The next levels above the zero modes are the **brane band**, the lowest even level of block type $j = +1$ in each shell $n_2 \geq 1$ (Section 15.4); in the free gas at $a_{4,0} = 0$ the band levels increase with n_2, so filling them shell by shell gives **closed shells** (every level either full or empty). Line by line, with $g = 4r_3(n_2)$:

$$8 + 4\big(r_3(1) + r_3(2) + r_3(3) + r_3(4)\big) = 8 + 4\,(6 + 12 + 8 + 6) = 8 + 128 = 136.$$

Rule: the eight zero modes plus four times the numbers of vectors in the shells 1 to 4. Continuing to $n_2 = 11$ with $r_3(5), \ldots, r_3(11) = 24, 24, 0, 12, 30, 24, 24$:

$$8 + 4\,(32 + 24 + 24 + 0 + 12 + 30 + 24 + 24) = 8 + 4 \cdot 170 = 688.$$

Rule: the sum $6 + 12 + 8 + 6 = 32$ of the first four shells plus the seven new shells. $N = 688$ is the largest closed shell whose highest level lies below the **bulk edge** 1.2922928, the lowest level that is not on the brane band (the odd level at $k = 0$; parameters.json, particleNumbers.bulkEdge; a value at the cutoff $L = 3$, see the end of this section); $N = 136$ is the closed shell nearest to $688/4 = 172$ (Exercise 1 checks this). The record calls 688 N_{large} and 136 N_{mid} (parameters.json, particleNumbers.N_large and particleNumbers.N_mid, with the rule in particleNumbers.rule).

The couplings. The coupling λ is a constant of the theory, the same at every slice. For each N the record chooses two values so that the interaction is a moderate perturbation along the whole history (parameters.json, couplingCalibration). In the free ground states of that N at all five slices it takes the largest value over y of $\max\left(\frac{15}{16}|S|, \frac{1}{16}n\right)$, the size of the mean-field potentials per unit λ (called the **strength**), and sets $\lambda_1 = 0.1/\text{strength}$ and $\lambda_2 = 0.3/\text{strength}$, rounded to four significant digits; then the first-order potentials stay below $0.1\,m$ and $0.3\,m$. For $N = 8$ the strength is 5.138804, so $\lambda_1 = 0.1/5.138804 = 0.019460$, rounded 0.01946, and $\lambda_2 = 0.05838$. For $N = 136$ and 688 the strengths are 107.548 and 541.713, so $\lambda_1 = 0.0009298$ and 0.0001846, $\lambda_2 = 0.002789$ and 0.0005538. The strength of $N = 136$ grows from 5.226 at the first slice to 107.548 at the last, that of $N = 688$ from 5.226 to 541.713 (parameters.json, strengthPerLambdaAtSlices): along the history the brane-band orbitals spread toward the tip, where the factor $P = e^{-6Hy}/\mathrm{Vol}_7$ is large. A calibration at the first slice alone would make the late states strongly coupled; this is why the whole history is used. The calibration is made at the cutoff $L = 3$, and the strength grows with L (the end of this section). The sign of λ decides the kind of interaction: $\lambda > 0$ is repulsive, $\lambda < 0$ attractive. The run names use the tags `lam0`, `lamp1`, `lamm1`, `lamp2`, `lamm2` for $\lambda = 0, +\lambda_1, -\lambda_1, +\lambda_2, -\lambda_2$.

The canonical matrix. The solver computes a fixed list of states. **Ground states** ($T = 0$): three particle numbers $N = 8, 136, 688$, five couplings and five slices $a_{4,0} = 0, 0.5, 1, 1.5, 2$, that is $3 \cdot 5 \cdot 5 = 75$ states. **Thermal states**: the same three N, the three couplings $0, \pm\lambda_1$, the five slices and three temperatures $T = 0.01, 0.02, 0.05$, that is $3 \cdot 3 \cdot 5 \cdot 3 = 135$ states. A state is named like `N136_lamp2_a20` ($N = 136$, $+\lambda_2$, $a_{4,0} = 2.0$; the last two digits are ten times the slice), and a thermal state carries in addition `_T10`, `_T20` or `_T50` (a thousand times the temperature).

The numerical parameters (parameters.json, numerics): $G = 900$ steps of the Runge-Kutta method on $[-L, 0]$, a root tolerance of $10^{-13}\,m$ for each level, a self-consistency tolerance of $10^{-11}\,m$

with at most 400 iterations, Anderson mixing with depth 6 and $\beta = 0.4$, the step $\delta = 0.002$ in a_4 for derivatives along the history, and levels closer than $10^{-9}\,m$ count as equal (one degenerate group).

What the cutoff $L = 3$ changes (the choice is CHOSEN, its effect COMPUTED). The regular tip and the value $L = 3$ are choices of the model, and the record measures what they change in the folder `Revision/kohn_sham/tip_convergence/`, summarised in sections 5 and 15 of the document `Revision/docs/KOHN_SHAM_DEFLATING_FIELD.md`. It solves 29 recorded states, the 27 ground states with $N = 8, 136, 688$, $\lambda = 0, \pm\lambda_1$, $a_{4,0} = 0, 1, 2$ and two thermal states of $N = 136$, at $L = 3, 3.5, \ldots, 6$ with the record's step $h = 1/300$, and every run again with the step $h/2$. A copy of the solver that reads L from the environment reproduces the committed matrix byte for byte at $L = 3$, and the independent reference solver agrees at $L = 3$ and $L = 4$ (report `Revision/kohn_sham/tip_convergence/tip-convergence.json`, 7 of 7 checks PASS).

How the study judges the limit $L \to \infty$. The rules were fixed before the comparison and changed once, after the first analysis (sections 3 and 9 of the README of that folder; the change is told after the rule). For each computed number x, for example E_{KS}, the study forms the **successive differences** $d = x(L + 0.5) - x(L)$ over the unbroken run $L = 3, 3.5, 4, \ldots$ of values at which the self-consistent iteration converged (the run ends just before the first L at which the iteration fails, and values at larger L after a failure are not used), and the ratio r of each difference to the one before it. If every difference from some L on is no larger than the numerical noise of its two values, the number has converged within the noise, and its last value is its limit. The noise of a value x_h computed with the step h is $\frac{16}{15}|x_{h/2} - x_h|$, measured with the run at the step $h/2$, plus 10^{-11} times the larger of 1 and $|x|$: the error of the Runge-Kutta rule, which is of fourth order, falls by the factor $2^4 = 16$ when the step is halved, so $x_h - x_{h/2}$ is $\frac{15}{16}$ of the error of x_h. If the last two ratios both lie between 0 and 0.5, the study takes the differences to go on shrinking like a geometric series, each one the fraction r (the last ratio) of the one before; this is the **geometric-tail rule**, and the limit, which the record calls the extrapolated value and this chapter also the large-L value, adds the differences still missing:

$$x_\infty = x(L_{max}) + d_{last}\,(r + r^2 + r^3 + \ldots) = x(L_{max}) + d_{last}\,\frac{r}{1 - r}.$$

Rule: L_{max} is the last L of this run and d_{last} the last difference, so the next differences would be $d_{last}r, d_{last}r^2, \ldots$; the sum $s = r + r^2 + r^3 + \ldots$ obeys $s = r + r\,s$ (take the factor r out of every term after the first), so $s = r/(1 - r)$ for $0 < r < 1$. In every other case, and when this run holds fewer than three values of L (as for $N = 688$, $+\lambda_1$, $a_{4,0} = 0$, which converges at $L = 3$ and fails at $L = 3.5$; its converged values at $L = 4$, 4.5 and 5 come after the failure and are not used), the study takes no limit: the limit is not established. This condition on the last two ratios is the one change of the rules (section 9 of the README). The first analysis accepted a geometric tail whenever the last ratio was below 0.9. That gave $N = 688$, $\lambda = 0$, $a_{4,0} = 0$ an extrapolated value, although its ratios 0.77 to 0.79 are those of a tail that falls like the power L^{-3}, not geometrically. The rule above is the stricter one, and the change only removed extrapolations. This rule follows the dependence on L; it is not the Richardson extrapolation of Chapter 2, which combines two values so that their leading error term cancels. What the study finds:

- The free results with $k \neq 0$ converge faster than exponentially, because an orbital with momentum k is suppressed toward the tip like $\exp\big(-|k|(\kappa(-L) - \kappa(y))/H\big)$. The recorded $L = 3$ values are low by up to 1.4 per cent in E_{KS} and 12 per cent in the integrated pressure along the hidden direction, $2\,\mathrm{Vol}_7 \int e^{6Hy} p_0\,dy$ (the record's column `int_p0`, Section 15.16):

for $N = 136$, $\lambda = 0$, $a_{4,0} = 2$ they are 12.44507 against the extrapolated 12.62207, and 8.47270 against 9.63839.

- The levels at $k = 0$ other than the zero mode approach $\pm m$ only slowly, like $(n\pi)^2/(2mL^2)$ (Section 15.3 derives this for the even levels from their exact formula; the record verifies the exact levels at every L of the study, 84 levels, to $1.42 \times 10^{-10}\, m$). So the bulk edge 1.2922928 that defines $N = 688$ is a value at $L = 3$: it is 1.0977 at $L = 6$ and tends to m as $L \to \infty$. From $L = 3.5$ on, the ground state of $N = 688$ at $a_{4,0} = 0$ occupies levels of the bulk at $k = 0$, its gap 0.0452 closes, and its energy does not converge up to $L = 6$.

- The interacting results depend strongly on L. The proper density of the zero modes grows toward the tip like $e^{(6H-2m)|y|} = e^{4|y|}$ (exact, and verified by the record; Figure 15e.6 shows the potential it makes). For $N = 8$ the record finds $E_{KS} = \mp 9.868 \times 10^{-4}$ at $L = 3$ ($\lambda = \pm\lambda_1$, every slice) against $\mp 3.0046 \times 10^{-3}$ at large L, extrapolated from $\lambda = -\lambda_1$ at $a_{4,0} = 2$, the only interacting $N = 8$ state solved up to $L = 6$ (the $\pm\lambda_1$ partners are negatives of each other to 1.1×10^{-12} relative at every L where both converge; the other interacting $N = 8$ states extrapolate to $\mp 3.007 \times 10^{-3}$ from $L \leq 4.5$, because their self-consistent iteration fails from $L = 5$): the recorded value is about one third of the large-L value. For $N = 136$ at $a_{4,0} = 2$ the interaction shift $E_{KS}(\pm\lambda_1) - E_{KS}(0)$ is about 21 times its value at $L = 3$ at large L for $-\lambda_1$ (extrapolated), and about 28 times at $L = 5.5$ for $+\lambda_1$ (the last L before its iteration fails; its limit is not established).

- The self-consistent iteration fails at some larger L for 13 of the 19 interacting states studied; this is a failure of the iteration, not a proof that no self-consistent state exists. For 7 of them the successive differences of E_{KS} do not meet the geometric-tail rule of the study before the iteration fails, so their limit is not established; for the other 6 the values before the failure still end in a geometric tail.

- The calibration of the couplings is a statement at $L = 3$: the strength is the largest first-order mean-field potential per unit λ, and it grows with L (for $N = 8$ it is the zero-mode potential at the tip, which grows like e^{4L}). The same rule applied at larger L drives λ_1 to zero: at $L = 6$ it gives 1.2×10^{-7} for $N = 8$ (falling like e^{-4L} from 0.01946 at $L = 3$), 1.2×10^{-7} for $N = 136$ and 1.0×10^{-11} for $N = 688$.

Not computed at $L \neq 3$: the couplings $\pm\lambda_2$, the slices 0.5 and 1.5, $T = 0.01$ and the other thermal states, the excited states and the adiabaticity measure; and nothing beyond $L = 6$. Every number printed by the notebooks of this chapter is a value at $L = 3$, and so is every number of the chapter except where this paragraph is cited.

15.3 Finding one level: shooting with the Pruefer angle

The idea of shooting. For a trial energy ε, start at the tip with values that satisfy the tip condition, $(a, b) = (1, 0)$, integrate the two first-order equations of Section 15.2 from $y = -L$ to $y = 0$ with a step rule (the Runge-Kutta rule RK4 of Chapter 2), and look at the end values. If the brane condition of the wanted parity holds there ($b(0) = 0$ or $a(0) = 0$), ε is a level. If not, change ε and shoot again. The start value 1 for a is no restriction: the equations are linear in (a, b), so any other start $(c, 0)$ gives c times the same solution, and the solution is normalised at the end.

Chapter 2 introduced this method for a quantum well. Two difficulties remain: how to find every level without missing one, and how to tell which level is which. The Pruefer angle solves both.

The Pruefer angle. Write the point (a, b) in polar form, $a = r\cos\theta$, $b = r\sin\theta$, with the length $r = \sqrt{a^2 + b^2} > 0$ and the angle θ, followed continuously along y (it may grow beyond 2π). We derive the equation for θ, line by line.

$$ab' - ba' = r\cos\theta\,(r'\sin\theta + r\cos\theta\,\theta') - r\sin\theta\,(r'\cos\theta - r\sin\theta\,\theta') = r^2\theta'.$$

Rule: differentiate $a = r\cos\theta$ and $b = r\sin\theta$ with the product and chain rules; the terms with r' cancel, and $\cos^2\theta + \sin^2\theta = 1$.

$$ab' = \big(j(\varepsilon - v) - \kappa k\big)a^2 - Mab, \qquad ba' = Mab - \big(\kappa k + j(\varepsilon - v)\big)b^2.$$

Rule: multiply the second block equation by a and the first by b.

$$ab' - ba' = j(\varepsilon - v)(a^2 + b^2) - \kappa k\,(a^2 - b^2) - 2Mab.$$

Rule: subtract; the terms with $j(\varepsilon - v)$ collect to $j(\varepsilon - v)(a^2 + b^2)$, the terms with κk to $-\kappa k a^2 + \kappa k b^2$, and the two terms $-Mab$ add.

$$\theta' = j(\varepsilon - v) - \kappa k\cos 2\theta - M\sin 2\theta.$$

Rule: divide by r^2 and use $a^2 + b^2 = r^2$, $a^2 - b^2 = r^2(\cos^2\theta - \sin^2\theta) = r^2\cos 2\theta$ and $2ab = 2r^2\cos\theta\sin\theta = r^2\sin 2\theta$ (the double-angle formulas). The angle obeys an equation of its own, without r. At the tip, $(a, b) = (1, 0)$ gives $\theta(-L) = 0$ for every ε.

The phase function. Define $\Phi(\varepsilon) = j\,\theta(0)$, j times the angle at the brane. The brane conditions become conditions on Φ: $b(0) = 0$ means $\sin\theta(0) = 0$, that is $\theta(0)$ is a whole multiple of π, so $\Phi = l\pi$ with a whole number l (even parity); $a(0) = 0$ means $\cos\theta(0) = 0$, so $\Phi = \frac{\pi}{2} + l\pi$ (odd parity). (Multiplying by $j = \pm 1$ maps the set of these values onto itself.) So every level is a solution of $\Phi(\varepsilon) = t_l$ for one of the **targets** $t_l = l\pi$ (even) or $t_l = \frac{\pi}{2} + l\pi$ (odd).

Φ increases strictly. We compute $u = \partial\theta/\partial\varepsilon$, line by line.

$$u' = j + \big(2\kappa k\sin 2\theta - 2M\cos 2\theta\big)\,u, \qquad u(-L) = 0.$$

Rule: differentiate the angle equation with respect to ε (chain rule: $\partial(\cos 2\theta)/\partial\varepsilon = -2\sin 2\theta\,u$ and $\partial(\sin 2\theta)/\partial\varepsilon = 2\cos 2\theta\,u$); $u(-L) = 0$ because $\theta(-L) = 0$ for every ε.

$$(\ln r)' = \frac{aa' + bb'}{r^2} = M\cos 2\theta - \kappa k\sin 2\theta.$$

Rule: $(\ln r)' = r'/r = (aa' + bb')/r^2$ (differentiate $r^2 = a^2 + b^2$); insert the block equations, where the terms with $j(\varepsilon - v)$ cancel: $aa' + bb' = M(a^2 - b^2) - 2\kappa k\,ab$; then the double-angle formulas.

$$u' = j - 2(\ln r)'\,u.$$

Rule: the bracket of the first line is -2 times the second line.

$$(r^2u)' = 2rr'u + r^2u' = r^2\big(2(\ln r)'u + j - 2(\ln r)'u\big) = j\,r^2.$$

Rule: the product rule, $r' = r\,(\ln r)'$, and the previous line.

$$r(0)^2\,u(0) = j\int_{-L}^{0} r^2\,dy, \qquad \frac{d\Phi}{d\varepsilon} = j\,u(0) = \frac{\int_{-L}^{0} r^2\,dy}{r(0)^2} > 0.$$

Rule: integrate from the tip to the brane, with $u(-L) = 0$; then multiply by j and use $j^2 = 1$. The result is positive because $r^2 = a^2 + b^2 > 0$. So Φ **increases strictly with** ε, for both block types, any potentials and any slice. This formula is also the derivative that Newton's method needs, and the solver computes it at no extra cost while it integrates (its documentation in `Revision/kohn_sham/solver/README.md`, Method).

Φ runs from $-\infty$ to $+\infty$. On the interval the functions $|v|$, κk and $|M|$ are bounded, say by a number C_0 each. Then $j\theta' = (\varepsilon - v) - j\kappa k\cos 2\theta - jM\sin 2\theta$ lies between $\varepsilon - 3C_0$ and $\varepsilon + 3C_0$, and integrating over the length L gives $(\varepsilon - 3C_0)L \le \Phi(\varepsilon) \le (\varepsilon + 3C_0)L$. So $\Phi(\varepsilon) \approx \varepsilon L$ for large $|\varepsilon|$, and it takes every real value.

The oscillation theorem. A continuous function that increases strictly from $-\infty$ to $+\infty$ takes every value exactly once. Hence each target t_l is reached at exactly one energy: **every level has its own whole number l, its Pruefer label, and no level can be missed.** In a sector the levels are ordered by their labels. When the potentials change continuously (from one iteration of the self-consistent loop to the next, when the coupling is switched on, or from one slice to the next), a level moves continuously and keeps its label, because the target does not change. The label is therefore a name that follows a level everywhere. The particle levels of a sector are exactly the labels $l \ge l_{min}$, where l_{min} is the first label whose level without interaction is positive; in the even sectors at $k = 0$, $l_{min} = 0$ is the zero mode, counted as a particle level by the convention of Section 15.2 (the solver checks this split in every sector up to $n_2 = 30$, check free_particle_branch_labels of `Revision/kohn_sham/reports/ks-rust-solver.json`).

The test case: exact levels at $k = 0$. With $k = 0$, $v = 0$ and a constant mass $M > 0$ the levels are known exactly (ks-theory.json, boundaryConditions.exactK0Spectra; check bc_exact_k0_spectra). Line by line:

$$a'' = Ma' - j\varepsilon b' = Ma' - j\varepsilon(j\varepsilon a - Mb) = Ma' - \varepsilon^2 a + j\varepsilon Mb.$$

Rule: differentiate the first block equation (with $k = 0$, $v = 0$) and insert the second; $j^2 = 1$.

$$a'' = Ma' - \varepsilon^2 a + M(Ma - a') = (M^2 - \varepsilon^2)\,a.$$

Rule: the first block equation says $j\varepsilon b = Ma - a'$. The same two steps for b, line by line:

$$b'' = j\varepsilon a' - Mb' = j\varepsilon(Ma - j\varepsilon b) - Mb' = j\varepsilon Ma - \varepsilon^2 b - Mb'.$$

Rule: differentiate the second block equation (with $k = 0$, $v = 0$) and insert the first; $j^2 = 1$.

$$b'' = M(b' + Mb) - \varepsilon^2 b - Mb' = (M^2 - \varepsilon^2)\, b.$$

Rule: the second block equation says $j\varepsilon a = b' + Mb$. For $\varepsilon \neq 0$ this relation gives a from b, so an orbital that is not zero everywhere has a b that is not zero everywhere; the cases $\varepsilon \neq 0$ are sorted by the sign of $M^2 - \varepsilon^2$. For $\varepsilon^2 > M^2$ put $p = \sqrt{\varepsilon^2 - M^2}$; then $b'' = -p^2 b$, and the tip condition $b(-L) = 0$ leaves $b = B \sin\big(p(y + L)\big)$ with $B \neq 0$. Even parity, $b(0) = 0$: $\sin(pL) = 0$, so $p = n\pi/L$ and

$$\varepsilon = \pm\sqrt{M^2 + (n\pi/L)^2}, \qquad n = 1, 2, \ldots$$

Odd parity, $a(0) = 0$: the second block equation gives $j\varepsilon a = b' + Mb$, so $a(0) = 0$ means $b'(0) + Mb(0) = 0$, that is $Bp\cos(pL) + MB\sin(pL) = 0$, or $\tan(pL) = -p/M$.

Inside the gap, $0 < \varepsilon^2 < M^2$, put $q = \sqrt{M^2 - \varepsilon^2} > 0$; then $b'' = q^2 b$. The functions $\cosh x = (e^x + e^{-x})/2$ and $\sinh x = (e^x - e^{-x})/2$ are each the derivative of the other, so $\cosh\big(q(y + L)\big)$ and $\sinh\big(q(y + L)\big)$ solve $b'' = q^2 b$, every solution is a combination of the two, and the tip condition $b(-L) = 0$ (where $\cosh 0 = 1$, $\sinh 0 = 0$) leaves $b = B \sinh\big(q(y + L)\big)$ with $B \neq 0$. Even parity needs $b(0) = B\sinh(qL) = 0$, impossible because $\sinh x > 0$ for $x > 0$. Odd parity needs $b'(0) + Mb(0) = B\big(q\cosh(qL) + M\sinh(qL)\big) = 0$, impossible because both terms in the bracket are positive. At the edge, $\varepsilon^2 = M^2$, the equation is $b'' = 0$ and the tip condition leaves $b = B(y + L)$; even parity needs $BL = 0$ and odd parity $b'(0) + Mb(0) = B(1 + ML) = 0$, both impossible for $B \neq 0$. So **no level lies in** $0 < |\varepsilon| \leq M$: the only level inside the gap is the zero mode. Finally $\varepsilon = 0$: the equations become $a' = Ma$, $b' = -Mb$, so $b = 0$ (from $b(-L) = 0$) and $a = Ce^{My}$: the **zero mode**, which satisfies the even brane condition. Normalising, $\int_{-L}^{0} C^2 e^{2My} dy = C^2(1 - e^{-2ML})/(2M) = 1$ gives $C = \sqrt{2M/(1 - e^{-2ML})}$. For $M = 1$, $L = 3$: the first even levels are $\pm\sqrt{1 + (\pi/3)^2} = \pm 1.4479719$, and the first odd level is ± 1.2922928, the bulk edge of Section 15.2. Notebook 15e reproduces all of them by shooting (Out [6]).

How these levels depend on the cutoff. Every level other than the zero mode depends on L. For the even levels, line by line:

$$\sqrt{M^2 + (n\pi/L)^2} - M = \frac{(n\pi/L)^2}{\sqrt{M^2 + (n\pi/L)^2} + M} \approx \frac{(n\pi)^2}{2ML^2} \quad (L \text{ large}).$$

Rule: multiply and divide by the sum $\sqrt{M^2 + (n\pi/L)^2} + M$ and use $(A - B)(A + B) = A^2 - B^2$; for large L the denominator tends to $2M$. So the levels at $k = 0$ approach $\pm M$ only like $1/L^2$, slowly; the record finds the same $1/L^2$ approach for the odd levels (the bulk edge is 1.2923 at $L = 3$ and 1.0977 at $L = 6$; Section 15.2, the paragraph on the cutoff). The zero mode stays at $\varepsilon = 0$ for every L; only its normalisation C depends on L.

Newton's method inside a bracket. To solve $\Phi(\varepsilon) = t_l$ the solver uses Newton's method, $\varepsilon \to \varepsilon - (\Phi(\varepsilon) - t_l)/\Phi'(\varepsilon)$, with the derivative from the formula above. Newton's method converges very fast near the root but can jump far away from a poor guess, so it is **safeguarded**: from a guess the solver first walks with doubling steps (up if $\Phi < t_l$, down otherwise) until $\Phi - t_l$ changes sign; the last two points form a **bracket** $[lo, hi]$ that contains the root, because Φ is continuous. Then it takes Newton steps, and replaces a Newton step by **bisection** (the midpoint of the bracket) whenever the Newton step would leave the bracket or the previous step did not halve $|\Phi - t_l|$; after

each step the bracket shrinks to the side where the sign changes. It stops when the bracket is shorter than the tolerance $10^{-13}\,m$ or when a Newton step moved the energy by less than that (Newton's method approaches a root from one side, so the bracket itself need not shrink). The levels are therefore found to about $10^{-13}\,m$ for a given grid.

The grid, RK4 and the order 4. The solver makes $G = 900$ steps of length $h = L/G = 1/300$. One RK4 step needs the coefficients M, v and κ at the start, the middle and the end of the step, so the potentials are stored on the **fine grid** of the $2G + 1 = 1801$ step ends and midpoints, $y_i = -L + i\,h/2$. The error of RK4 falls like h^4 (Chapter 2): halving the step divides it by $2^4 = 16$. The record measured exactly this ratio, 16.00, between its canonical run ($G = 900$) and a refined run ($G = 1800$) (check refined_free_spectra_convergence_order of `Revision/kohn_sham/reports/ks-rust-determinism.json`).

The orbital between the step ends: cubic Hermite interpolation. RK4 gives (a, b) at the step ends only, but the densities are needed on the whole fine grid. Each midpoint value is filled in from the values u_0, u_1 and the derivatives u_0', u_1' at the two ends of a step (the derivatives come from the block equation itself). Take a cubic polynomial and measure from the midpoint, $p(s) = A + Bs + Cs^2 + Ds^3$, $-h/2 \le s \le h/2$, so that the wanted value is $p(0) = A$. Line by line:

$$u_0 + u_1 = p(-h/2) + p(h/2) = 2A + \tfrac{h^2}{2}C.$$

Rule: in the sum of the two end values the odd powers of s cancel and the even powers double.

$$u_1' - u_0' = p'(h/2) - p'(-h/2) = 2Ch.$$

Rule: $p'(s) = B + 2Cs + 3Ds^2$; in the difference only the term $2Cs$ survives.

$$A = \frac{u_0 + u_1}{2} - \frac{h^2}{4}C = \frac{u_0 + u_1}{2} - \frac{h^2}{4}\cdot\frac{u_1' - u_0'}{2h} = \frac{u_0 + u_1}{2} + \frac{h}{8}\,(u_0' - u_1').$$

Rule: solve the first line for A and insert C from the second. The formula is exact for every cubic polynomial, so its error is of the order h^4, like RK4 itself.

Normalisation with Simpson's rule. The integral $\int_{-L}^{0}(a^2 + b^2)\,dy$ is computed with Simpson's rule on the fine grid: the weights are $\frac{h}{6}$ times $1, 4, 2, 4, \ldots, 2, 4, 1$ (Simpson's rule of Chapter 2 with the spacing $h/2$, whose weights are $\frac{h/2}{3}$ times the same numbers). Its error is also of the order h^4. The orbital is then divided by the square root of the integral.

A detail that matters for Newton's method. For the derivative $d\Phi/d\varepsilon = \int r^2 dy / r(0)^2$ the solver integrates r^2 with the simpler **trapezoid rule** on the step ends while it shoots ($\frac{h}{2}(r_i^2 + r_{i+1}^2)$ per step). This derivative only steers Newton's method; an error in it changes how fast the root is found, not where it is.

15.4 From one level to the whole gas

Label sets. For a state of the gas the solver chooses the sectors and labels it will solve, its **label set**. It takes the shells $n_2 = 0, 1, 2, \ldots$ in turn, with all four sectors (two block types, two parities) of each shell, fills the free levels found so far from the lowest upward, and stops adding shells

when the lowest level of a new shell lies more than a margin above the lowest empty level (the LUMO) of that filling (in the canonical runs the margin is $0.25\,m$ plus twice the target size $0.1\,m$ or $0.3\,m$ of the coupling's first-order potential); in the occupied shells and the next one it solves three particle labels per sector, elsewhere the lowest only (`Revision/kohn_sham/solver/src/scf.rs`, the function `specs_t0`). The check ground_window_complete of the solver's report confirms for all 75 ground states that the lowest level outside the label set lies above the LUMO of the converged state, so no level that matters was left out.

The brane band. For $k > 0$ the lowest even level of block type $j = +1$ (label 0) grows out of the zero mode: it is bound to the brane, and its energy grows with k. This is the **brane band**. Its slope at $k = 0$ is known exactly (ks-theory.json, checksNumeric; check brane_band_slope):

$$\frac{d\varepsilon}{dk}\Big|_{k=0} = c\,e^{-a_{4,0}}, \qquad c = \frac{2M}{2M-H}\cdot\frac{1-e^{-(2M-H)L}}{1-e^{-2ML}}.$$

For $M = H = 1$ and $L = 3$, line by line:

$$c = \frac{2}{1}\cdot\frac{1-e^{-3}}{1-e^{-6}} = \frac{2\,(1-e^{-3})}{(1-e^{-3})(1+e^{-3})} = \frac{2}{1+e^{-3}} = 1.9051482536.$$

Rule: $2M - H = 1$; then $1 - e^{-6} = (1 - e^{-3})(1 + e^{-3})$ (the difference of two squares), and the common factor cancels; $e^{-3} = 0.0497871$.

The two block types and the sea. Without interaction the two block types mirror each other: $h_{-1} = -h_{+1}$ as operators with the same boundary conditions (check block_type_relation), so every orbital of $j = +1$ is also an orbital of $j = -1$, with the same k and parity and the opposite level. The band of $j = -1$ therefore lies at $-\varepsilon_{band}(k)$, below zero: it belongs to the sea, and the positive band levels are those of $j = +1$ only, each $4r_3(n_2)$-fold. At $k = 0$ the zero mode ($\varepsilon = 0 = -0$) belongs to both types, so the zero-mode level is $4 + 4 = 8$-fold.

The rescaling identity and the redshift. The slice enters the block equation only through $\kappa k = e^{-Hy}(k\,e^{-a_{4,0}})$. Therefore (ks-theory.json, rescalingIdentity; check rescaling_identity), without interaction,

$$\varepsilon(k;\ a_{4,0}) = \varepsilon(k\,e^{-a_{4,0}};\ 0)$$

for every level: a later slice is the first slice with every 3-momentum **redshifted** by $e^{-a_{4,0}}$. With interaction the same holds for the whole self-consistent state when the extra-time volume is changed too (Chapter 14); the solver solved each partner problem independently and found the same levels to $1.5 \times 10^{-13}\,m$ (check rescaling_identity_between_slices of `Revision/kohn_sham/reports/ks-rust-solver.json`). Three consequences:

- The levels at $k = 0$ (the zero modes and the bulk levels at $k = 0$) do not depend on the slice at all.
- The brane band increases with k (the solver checks this on $0 \le k \le 4$, check free_rescaling_relation_and_band_monotone). A level of the band at a fixed shell therefore decreases strictly along the history, because its redshifted momentum $k\,e^{-a_{4,0}}$ decreases.

- Every energy of the free gas that comes from band levels falls along the history.

The gap of $N = 8$, exactly. For $N = 8$ the highest occupied level is the zero mode ($\varepsilon = 0$) and the lowest empty one is the band level of the first shell, $k = \Delta k = 0.25$. So the Kohn-Sham gap is

$$\Delta_{KS}(a_{4,0}) = \varepsilon_{band}(0.25\, e^{-a_{4,0}};\ 0).$$

The record gives 0.4307337, 0.1703493 and 0.0641594 at $a_{4,0} = 0, 1, 2$ (Notebook 15a, Out [7]). The ratios to the first value are 0.39549 and 0.14895, larger than $e^{-1} = 0.36788$ and $e^{-2} = 0.13534$: the gap shrinks somewhat more slowly than $e^{-a_{4,0}}$. The reason is visible in Figure 15e.4: the band bends below its tangent line $c\,k$, so $\varepsilon_{band}(k)/k$ decreases with k; a redshifted momentum lies where the ratio is larger, closer to c. Exercise 2 makes this precise.

Aufbau and closed shells. At $T = 0$ the solver fills the levels from the lowest upward, with exact groups of equal levels (levels within $10^{-9}\,m$ count as equal); a group that would be filled only in part is flagged as an **open shell**. The particle numbers of Section 15.2 were chosen as closed shells, and the check ground_closed_shell confirms for all 75 ground states that no group is partly filled.

15.5 Self-consistency, the energy, and the first excited state

The loop. The unknowns of the self-consistent problem are the two functions $M(y) - m$ and $v(y)$ on the 1801 points of the fine grid, collected in one long list x of 2×1801 numbers (the solver keeps a third function for a variant with the exact Fock exchange, zero in the canonical functional). One **iteration**: (1) from the input x, solve every level of the label set (Section 15.3); (2) fill them (aufbau at $T = 0$, Fermi-Dirac at $T > 0$); (3) build the densities n and S and from them the output potentials $x_{out} = (\frac{15}{16}\lambda S,\ -\frac{1}{16}\lambda n)$; (4) the **residual** is $r = x_{out} - x$, and its size is its largest entry in absolute value. The loop stops when this size is at most $10^{-11}\,m$. Without interaction $x_{out} = 0 = x$ after one iteration.

Mixing. Taking x_{out} as the next input (plain iteration) can oscillate forever (charge sloshing, Chapter 13). **Linear mixing** takes $x + \beta r$ with $0 < \beta < 1$. **Anderson mixing** remembers the last few inputs $x_1, \ldots, x_p$ and their residuals $r_1, \ldots, r_p$ ($p \le 6$ in the solver), finds numbers $c_1, \ldots, c_p$ with $\sum c_i = 1$ that make the combined residual $\sum c_i r_i$ as small as possible, and takes

$$x_{next} = \sum_i c_i\,(x_i + \beta\, r_i), \qquad \beta = 0.4.$$

The weights, line by line. We minimise $F(c) = |\sum_i c_i r_i|^2 = \sum_{i,k} c_i c_k\, G_{ik}$, with the **Gram matrix** $G_{ik} = r_i \cdot r_k$ (the dot product of two lists, the sum of the products of their entries), under the condition $\sum_i c_i = 1$. With a Lagrange multiplier ν (Chapter 13) we make $F - 2\nu(\sum_i c_i - 1)$ stationary:

$$\frac{\partial}{\partial c_i}\Big[\sum_{k,l} c_k c_l G_{kl} - 2\nu\Big(\sum_k c_k - 1\Big)\Big] = 2\sum_k G_{ik} c_k - 2\nu = 0.$$

Rule: each c_i appears in the double sum once as c_k and once as c_l, and G is symmetric ($r_i \cdot r_k = r_k \cdot r_i$), so the two terms are equal.

$$\begin{pmatrix} G & \mathbf{1} \\ \mathbf{1}^T & 0 \end{pmatrix} \begin{pmatrix} c \\ -\nu \end{pmatrix} = \begin{pmatrix} 0 \\ 1 \end{pmatrix}.$$

Rule: divide by 2, move ν to the left as the last unknown (with the sign it carries), and add the condition $\sum_k c_k = 1$ as the last row; $\mathbf{1}$ is the column of p ones. This is a small linear system of $p+1$ equations. The solver adds 10^{-12} times the largest diagonal entry of G to the diagonal (which keeps the system solvable when two residuals are nearly equal), drops the oldest pair when it still cannot be solved, and forgets the whole history when a residual grows to more than ten times the smallest seen so far (`Revision/kohn_sham/solver/src/scf.rs`). Notebook 15e writes the same rule in Python (without the fallback for an unsolvable system, which its runs never need), and Figure 15e.5 shows how much faster it converges than linear mixing. Exercise 4 works the weights out for $p = 2$.

The energy: why the interaction energy is subtracted. The energy of the interacting gas is its kinetic and mass energy plus the interaction energy. Each level ε already contains the potential energy of its orbital in the mean field, so the sum $\sum g f \varepsilon$ counts the interaction twice. Line by line, with $\langle\cdot\rangle$ meaning $2\,\mathrm{Vol}_7 \int_{-L}^{0} e^{6Hy}(\cdot)\,dy$ (the amount in the whole doubled box):

$$\sum g f\, \varepsilon = E_{kin} + \big\langle (M-m)S + v\, n \big\rangle.$$

Rule: the level is the expectation value of the block Hamiltonian; the terms of h with $M - m$ and v give, summed with $wgfP$ over the occupied orbitals, the densities S and n times the potentials (the definitions of S and n in Section 15.2); everything else ($-i\sigma_1 d/dy$, $m\sigma_2$, $\kappa k \sigma_3$) is collected in E_{kin}.

$$(M-m)S + v\, n = S\frac{\partial e_{int}}{\partial S} + n\frac{\partial e_{int}}{\partial n} = \lambda\Big(\tfrac{15}{16}S^2 - \tfrac{1}{16}n^2\Big) = 2\, e_{int}.$$

Rule: the potentials are the derivatives of e_{int} (Section 15.2), and e_{int} is a sum of squares, homogeneous of degree 2 (Euler's rule: $S\,\partial_S e + n\,\partial_n e = 2e$ for such a function); compare the coefficients $\frac{15}{16} = 2 \cdot \frac{15}{32}$ and $\frac{1}{16} = 2 \cdot \frac{1}{32}$.

$$E = E_{kin} + \langle e_{int} \rangle = \sum g f \varepsilon - 2\langle e_{int}\rangle + \langle e_{int}\rangle = \sum g f \varepsilon - 2\,\mathrm{Vol}_7 \int_{-L}^{0} e^{6Hy} e_{int}\, dy.$$

Rule: insert the first two lines. This is E_{KS} of Section 15.2 (ks-theory.json, thermodynamics.energy; check ks_onshell_lagrangian for the same degree-2 identity). The solver also computes the **variational form**, $\sum g f \varepsilon - \langle (M_{in} - m) S_{out} + v_{in} n_{out} \rangle + \langle e_{int}(S_{out}, n_{out}) \rangle$, with the input potentials and output densities of the last iteration; the two agree to 2.2×10^{-13} relative in all 75 ground states (check ground_energy_two_forms).

An exact symmetry of the zero-mode state. For $N = 8$ the eight occupied orbitals are the zero modes at $k = 0$. We show that changing the sign of λ changes the sign of the energy, $E_{KS}(-\lambda) = -E_{KS}(\lambda)$. Line by line:

- At $k = 0$ the block equations of type j are $a' = Ma - j(\varepsilon - v)b$ and $b' = j(\varepsilon - v)a - Mb$. Rule: Section 15.2 with $k = 0$.

- Put $\tilde{a} = a$, $\tilde{b} = -b$, $\tilde{\varepsilon} = -\varepsilon$, $\tilde{v} = -v$ and keep M and j. Then $\tilde{\varepsilon} - \tilde{v} = -(\varepsilon - v)$, and $\tilde{a}' = M\tilde{a} - j(\tilde{\varepsilon} - \tilde{v})\tilde{b}$, $\tilde{b}' = j(\tilde{\varepsilon} - \tilde{v})\tilde{a} - M\tilde{b}$. Rule: in each equation the two sign changes ($b \to -b$ and $\varepsilon - v \to -(\varepsilon - v)$) cancel.
- So $(a, -b)$ is an orbital of the problem with $(M, -v)$ at the level $-\varepsilon$, with the same boundary conditions ($b = 0$ stays $b = 0$) and the same label (the angle θ becomes $-\theta$, so $\Phi \to -\Phi$, and the zero-mode label 0 stays 0). Rule: the previous line and the definition of the label.
- Its density $a^2 + b^2$ is unchanged and its scalar density $2jab$ changes sign: $n \to n$, $S \to -S$. Rule: the definitions of Section 15.2.
- With $-\lambda$ the potentials made by these densities are $\frac{15}{16}(-\lambda)(-S) = M - m$ and $-\frac{1}{16}(-\lambda)n = -v$: exactly the potentials assumed. So the mapped orbitals form a self-consistent state of $-\lambda$. Rule: the formulas of M and v.
- Its energy: every level changes sign, so $\sum gf\varepsilon$ does; $e_{int} = \lambda(\frac{15}{32}S^2 - \frac{1}{32}n^2)$ changes sign with λ while S^2 and n^2 stay. Hence $E_{KS}(-\lambda) = -E_{KS}(\lambda)$. Rule: the energy formula above.

This is PROVED for the mapped state; that the loop started from the free state finds exactly this state is COMPUTED (Notebook 15e finds $|E(+\lambda) + E(-\lambda)| = 0$ exactly, Out [13], and the record lists $E_{KS} = \mp 9.8684262 \times 10^{-4}$ for $\pm\lambda_1$). These are values at the cutoff $L = 3$; the record's study of larger L finds the partners negatives of each other at every L where both converge, and the energy about three times larger at large L (Section 15.2, the paragraph on the cutoff). The symmetry is special to the zero modes: for larger N the band orbitals have $k \neq 0$, the momentum term spoils the map, and repulsion raises the energy while attraction lowers it.

The first excited state: Delta-SCF. Chapter 13 defined the Kohn-Sham gap $\Delta_{KS} = \varepsilon_{LUMO} - \varepsilon_{HOMO}$ and the Delta-SCF energy $\Delta_{SCF} = E_1 - E_0$, the difference of two self-consistent energies, the second with one particle moved from the highest occupied level to the lowest empty one. The solver uses an **ensemble** form: it removes one particle uniformly from the whole highest occupied group of equal levels and adds it uniformly to the whole lowest empty group, so that every orbital of a group keeps the same occupation and the block and direction symmetry of the reduction is kept (parameters.json, conventions.deltaScf). Without interaction the levels do not depend on the occupations, so $\Delta_{SCF} = \Delta_{KS}$ exactly (Janak's theorem of Chapter 13 with constant levels); the solver checks this in all 15 free states (check excited_delta_scf_free_equals_gap, largest difference $2.0 \times 10^{-11}\, m$). With interaction the orbitals relax and the two differ by the **orbital relaxation** $\Delta_{SCF} - \Delta_{KS}$; for example for `N8_lamp2_a00` the record has $\Delta_{KS} = 0.4312996$ and $\Delta_{SCF} = 0.4312929$ (`Revision/kohn_sham/results/excited/summary.csv`).

15.6 Example: the solver's method by hand (Notebook 15e)

Notebook 15e writes the method of Sections 15.3 to 15.5 in plain Python, exactly as the Rust solver does it (`Revision/kohn_sham/solver/src/shoot.rs` and `scf.rs`), and reproduces numbers of the record: the grid and Simpson's rule; one shooting integration with the Pruefer angle; the phase function and the levels it labels (Figure 15e.1); Newton's method inside a bracket, the exact levels at $k = 0$ and the solver's own levels; the orbitals with Hermite midpoints (Figure 15e.2); the order 4 of RK4 (Figure 15e.3); the brane band, its slope and the rescaling identity (Figure 15e.4); the self-consistent loop with Anderson mixing for $N = 8$, compared with linear mixing (Figure 15e.5); the four couplings and the symmetry $E(-\lambda) = -E(\lambda)$; and the self-consistent potentials (Figure

15e.6). It needs no Rust, runs in less than half a minute, and ends with ALL 18 CHECKS PASSED (notebook 15e).

What to look for: in Figure 15e.1 the steadily rising curve and the places where it crosses the horizontal lines (each crossing is one level, and none can be skipped); in Figure 15e.3 the straight lines of slope 4; in Figure 15e.4 the three band curves that are copies of each other with the momentum axis stretched; in Figure 15e.5 the blue dots, which fall on average about tenfold per iteration, and the black crosses of the Rust solver on top of them.

15.7 How to run Notebook 15e

Step 1. What this notebook does and what it needs.

Notebook 15e (The solver's method by hand: shooting, Pruefer count and Anderson mixing) is the file `Revision/textbook/notebooks/15e_shooting_by_hand.ipynb` of the repository Dirac_claude. It re-implements in plain Python the numerical method of the Rust Kohn-Sham solver (fourth-order Runge-Kutta shooting in the hidden coordinate, the Pruefer angle that labels every level, a safeguarded Newton root, the normalisation of the orbitals, and the self-consistent loop with Anderson mixing), and uses it to reproduce the solver's exact free spectra, its convergence order, the slope of the brane band and the interacting ground states of N = 8 particles from the committed Revision record. It needs a computer with Windows 11, macOS or Linux, an internet connection for the installation, the program Git, and Python 3.12 or newer (the notebooks were built with Python 3.14.5) with these packages at exactly these versions: numpy 2.4.6, sympy 1.14.0, mpmath 1.3.0, matplotlib 3.11.0, jupyterlab 4.4.10, nbformat 5.10.4, nbclient 0.10.2, ipykernel 7.1.0 and nbconvert 7.16.6. The notebook itself imports numpy and matplotlib; the other packages run Jupyter, the program that shows and runs notebooks. It does not need Rust.

Step 2. Install Git and Python (once per computer).

A terminal is the window in which you type commands: on Windows the app Windows PowerShell (or Terminal), on macOS the app Terminal (it runs the shell zsh), on Linux any terminal (it runs the shell bash). Type every command of this section into a terminal exactly as printed, one line at a time, and press Enter after each line.

Windows: download Git from https://git-scm.com/download/win and install it with the default choices. Download Python from https://www.python.org/downloads/ and run the installer; in its first window tick the box "Add python.exe to PATH" before you click "Install Now".

macOS: download Python from https://www.python.org/downloads/ and run the installer. Then open the app Terminal and run this command, which installs Git and the compiler tools:

macOS (zsh):

```
xcode-select --install
```

Linux (Debian or Ubuntu; other distributions have packages of the same names): run these two commands:

Linux (bash):

```
sudo apt update
sudo apt install git python3 python3-venv
```

Then close the terminal and open a NEW one (a terminal opened before the installation does not know the new programs), and check the version of Python; it must print 3.12 or a higher number:

Windows (PowerShell):

```
py -3 --version
```

macOS (zsh) and Linux (bash):

```
python3 --version
```

If an older Linux prints a lower number (Ubuntu 22.04 has Python 3.10), install Python 3.12 with the following three commands, and in Step 3 type `python3.12` instead of `python3` in the command that creates the environment:

Linux (bash), only when the version is too low:

```
sudo add-apt-repository ppa:deadsnakes/ppa
sudo apt update
sudo apt install python3.12 python3.12-venv
```

Step 3. Get the repository and install the packages (once per computer).

The commands below download the repository (a few hundred megabytes; the folder then needs up to about 1 GB of disk space) into the folder Dirac_claude inside your home folder, create a private Python environment in the folder dirac-book-env inside your home folder (a private environment is a folder with its own copy of Python and of the packages, so that nothing else on your computer is changed), activate it (from then on the commands `python` and `jupyter` typed in this terminal are those of the environment, and the prompt starts with (dirac-book-env)), and install the packages at the pinned versions (this downloads about 90 MB and takes a few minutes; the environment takes about 400 MB of disk space). If you have done this step before, for this or for another notebook, skip it and go to Step 4; to get the newest version of the repository, run `git pull` in the repository folder after Step 4.

Windows (PowerShell):

```
cd $HOME
git clone https://github.com/once-ere/Dirac_claude.git
py -3 -m venv "$HOME\dirac-book-env"
Set-ExecutionPolicy -ExecutionPolicy RemoteSigned -Scope Process -Force
& "$HOME\dirac-book-env\Scripts\Activate.ps1"
python -m pip install --upgrade pip
python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
```

The line with `Set-ExecutionPolicy` allows PowerShell to run the activation script in this one window only; it changes nothing permanently.

macOS (zsh):

```
cd ~
git clone https://github.com/once-ere/Dirac_claude.git
python3 -m venv ~/dirac-book-env
source ~/dirac-book-env/bin/activate
python -m pip install --upgrade pip
python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
```

Linux (bash):

```
cd ~
git clone https://github.com/once-ere/Dirac_claude.git
python3 -m venv ~/dirac-book-env
source ~/dirac-book-env/bin/activate
python -m pip install --upgrade pip
python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
```

Step 4. In every new terminal: activate the environment and go into the repository folder.

Every later step starts in the repository folder with the environment active. Run these lines whenever you open a new terminal (they do no harm if the environment is already active):

Windows (PowerShell):

```
Set-ExecutionPolicy -ExecutionPolicy RemoteSigned -Scope Process -Force
& "$HOME\dirac-book-env\Scripts\Activate.ps1"
cd "$HOME\Dirac_claude"
```

macOS (zsh) and Linux (bash):

```
source ~/dirac-book-env/bin/activate
cd ~/Dirac_claude
```

Step 5. Run the notebook in JupyterLab.

In the repository folder, with the environment active, run these two lines (the first one goes into the folder of the notebooks):

Windows, macOS and Linux:

```
cd Revision/textbook/notebooks
jupyter lab 15e_shooting_by_hand.ipynb
```

JupyterLab opens in your web browser and shows the notebook (if no browser window opens, copy the address that starts with `http://localhost:8888/lab` from the terminal into the address bar of your browser). The name at the top right of the notebook must read Python 3 (ipykernel). Choose the menu Run > Run All Cells. While a cell runs, the label to its left shows `[*]`; when it has finished, the label shows a number. The notebook has finished when the last code cell shows a number; this takes about 25 seconds on a typical laptop. Scroll to the end and compare the last printed lines with the lines in the step "What the notebook writes and what you must see" below. To keep the results, save the notebook (menu File > Save Notebook). To stop JupyterLab, choose the menu File > Shut Down, or press Ctrl+C twice in the terminal.

Step 6. Or run the notebook without a browser (headless).

In the repository folder, with the environment active, run:

Windows, macOS and Linux:

```
cd Revision/textbook/notebooks
jupyter nbconvert --to notebook --execute --inplace 15e_shooting_by_hand.ipynb
```

This runs every cell from the top to the bottom and saves the results into the notebook file. A failed check stops it with an error message that contains AssertionError and the name of the check. If the command ends with a line that starts with `[NbConvertApp] Writing` and shows no error, every check passed; open the notebook with `jupyter lab 15e_shooting_by_hand.ipynb` (in the same folder, without running the cells again) to read the printed lines and see the figures.

Step 7. What the notebook writes and what you must see.

The notebook writes (or overwrites) these files:

- `Revision/textbook/figures/15e.captions.json`
- `Revision/textbook/figures/15e_1_phase_function.png`
- `Revision/textbook/figures/15e_2_orbitals.png`
- `Revision/textbook/figures/15e_3_rk4_convergence.png`
- `Revision/textbook/figures/15e_4_brane_band.png`
- `Revision/textbook/figures/15e_5_scf_mixing.png`
- `Revision/textbook/figures/15e_6_n8_potentials.png`

It changes no other file of the repository; running it headless or saving it in JupyterLab also rewrites the notebook file itself. It does not use the internet while it runs. The files it writes are the same files that are stored in the repository (on another computer a figure may differ in a few bytes, which is harmless). To get the stored versions back, run this command in the repository folder (it also undoes every change you made yourself in the folder Revision/textbook):

Windows, macOS and Linux:

```
git checkout -- Revision/textbook
```

Every check of the notebook prints a line that starts with PASS. At the end of the notebook (the output of its last code cell) you must see exactly these lines:

```
PASS every figure file of this notebook exists
ALL 18 CHECKS PASSED (notebook 15e)
```

and the notebook must show 6 figures below the cells that draw them.

Step 8. If something goes wrong.

- "ModuleNotFoundError: No module named ..." in the notebook: JupyterLab was started without the environment. Stop it (menu File > Shut Down), do Step 4, and start it again. If the error remains, another Python installation has registered its own kernel called python3; with the environment active, run the following command and start JupyterLab again:

```
python -m ipykernel install --user --name python3
```

- "FileNotFoundError: The repository folder was not found": the notebook was opened from a copy outside the repository. Open the file `Revision/textbook/notebooks/15e_shooting_by_hand.ipynb` inside the folder Dirac_claude.
- "fatal: destination path 'Dirac_claude' already exists" in Step 3: the repository was downloaded before; skip the line with `git clone`.
- Windows: "running scripts is disabled on this system": run the line with `Set-ExecutionPolicy` and then the activation line again. "py is not recognized": use `python` instead of `py -3`; "python is not recognized": install Python again and tick "Add python.exe to PATH".
- Linux: "ensurepip is not available" when the environment is created: run `sudo apt install python3-venv` and repeat Step 3.
- "jupyter is not recognized" or "command not found: jupyter": the environment is not active; do Step 4. If the environment is active and the message stays, the programs jupyter-lab and jupyter-nbconvert are not in the folders where the terminal looks for programs (`python -m jupyter` does not help then: it has to find the same programs). Start them through Python itself, in the folder of the notebook: the first command below does what `jupyter lab` does, the second what the headless command does:

```
python -m jupyterlab 15e_shooting_by_hand.ipynb
python -m nbconvert --execute --inplace 15e_shooting_by_hand.ipynb
```

- Windows: the headless run prints a RuntimeWarning that mentions the "Proactor event loop" and zmq: this is a message of the package pyzmq, not an error; the run continues normally.
- A red box with "Matplotlib is building the font cache; this may take a moment." in the first run after the installation: this is a message, not an error; the run continues and the message does not come again.
- An AssertionError names a check that failed: choose the menu Kernel > Restart Kernel and Run All Cells; if it fails again, install the packages again with the pip commands of Step 3, because a different package version can change the last digits of a result.

15.8 Notebook 15e: complete text

This section prints the complete text of the notebook file `Revision/textbook/notebooks/15e_shooting_by_hand.ipynb`: every cell in order, with the output that the stored, executed notebook holds. A text cell (Jupyter calls it a markdown cell) is printed in a frame after the label Text cell. A code cell is printed after the label In [k], where k is the number that Jupyter gives the cell when it runs it; the text that the cell prints follows after the label Out [k], and every figure that the cell draws follows as a figure with its caption.

Text cell:

```
## 1. What this notebook computes

The Rust Kohn-Sham solver of the repository finds the levels and orbitals of the
Kohn-Sham equations of dirac16complex by **shooting**, labels every level with an
integer (the **Pruefer label**), and makes the potentials self-consistent with
**Anderson mixing**. This notebook writes the same method in plain Python, step by
step, and reproduces numbers of the committed Revision record:

- the exact levels at $k = 0$ (formulas) and the solver's numerical levels;
- the order of accuracy of the integration (the error falls 16-fold when the step is
  halved);
- the slope $c = 1.9051482536$ of the brane band and its redshift along the
  deflating history;
- the self-consistent ground states of $N = 8$ particles for the four couplings
  $\pm\lambda_1$, $\pm\lambda_2$: energies, levels and even the residual of each
  iteration of the loop;
- an exact symmetry of these states: $E_{KS}(-\lambda) = -E_{KS}(+\lambda)$.

It draws six figures. It needs no Rust: the Python code is short enough to read in
full, and it is slower than the solver only by a factor of about a hundred.
```

Text cell:

```
## 2. How to run this notebook

**Step 1. What this notebook does and what it needs.**

Notebook 15e (The solver's method by hand: shooting, Pruefer count and Anderson mixing)
is the file `Revision/textbook/notebooks/15e_shooting_by_hand.ipynb` of the repository
Dirac_claude. It re-implements in plain Python the numerical method of the Rust Kohn-Sham
solver (fourth-order Runge-Kutta shooting in the hidden coordinate, the Pruefer angle
that labels every level, a safeguarded Newton root, the normalisation of the orbitals,
and the self-consistent loop with Anderson mixing), and uses it to reproduce the solver's
exact free spectra, its convergence order, the slope of the brane band and the
interacting ground states of N = 8 particles from the committed Revision record. It needs
a computer with Windows 11, macOS or Linux, an internet connection for the installation,
the program Git, and Python 3.12 or newer (the notebooks were built with Python 3.14.5)
with these packages at exactly these versions: numpy 2.4.6, sympy 1.14.0, mpmath 1.3.0,
matplotlib 3.11.0, jupyterlab 4.4.10, nbformat 5.10.4, nbclient 0.10.2, ipykernel 7.1.0
and nbconvert 7.16.6. The notebook itself imports numpy and matplotlib; the other
packages run Jupyter, the program that shows and runs notebooks. It does not need Rust.
```

Step 2. Install Git and Python (once per computer).

A terminal is the window in which you type commands: on Windows the app Windows PowerShell (or Terminal), on macOS the app Terminal (it runs the shell zsh), on Linux any terminal (it runs the shell bash). Type every command of this section into a terminal exactly as printed, one line at a time, and press Enter after each line.

Windows: download Git from https://git-scm.com/download/win and install it with the default choices. Download Python from https://www.python.org/downloads/ and run the installer; in its first window tick the box "Add python.exe to PATH" before you click "Install Now".

macOS: download Python from https://www.python.org/downloads/ and run the installer. Then open the app Terminal and run this command, which installs Git and the compiler tools:

macOS (zsh):

```
xcode-select --install
```

Linux (Debian or Ubuntu; other distributions have packages of the same names): run these two commands:

Linux (bash):

```
sudo apt update
sudo apt install git python3 python3-venv
```

Then close the terminal and open a NEW one (a terminal opened before the installation does not know the new programs), and check the version of Python; it must print 3.12 or a higher number:

Windows (PowerShell):

```
py -3 --version
```

macOS (zsh) and Linux (bash):

```
python3 --version
```

If an older Linux prints a lower number (Ubuntu 22.04 has Python 3.10), install Python 3.12 with the following three commands, and in Step 3 type ‘python3.12‘ instead of ‘python3‘ in the command that creates the environment:

Linux (bash), only when the version is too low:

```
sudo add-apt-repository ppa:deadsnakes/ppa
sudo apt update
sudo apt install python3.12 python3.12-venv
```

Step 3. Get the repository and install the packages (once per computer).

The commands below download the repository (a few hundred megabytes; the folder then needs up to about 1 GB of disk space) into the folder Dirac_claude inside your home

folder, create a private Python environment in the folder dirac-book-env inside your home folder (a private environment is a folder with its own copy of Python and of the packages, so that nothing else on your computer is changed), activate it (from then on the commands ‘python‘ and ‘jupyter‘ typed in this terminal are those of the environment, and the prompt starts with (dirac-book-env)), and install the packages at the pinned versions (this downloads about 90 MB and takes a few minutes; the environment takes about 400 MB of disk space). If you have done this step before, for this or for another notebook, skip it and go to Step 4; to get the newest version of the repository, run ‘git pull‘ in the repository folder after Step 4.

Windows (PowerShell):

```
cd $HOME
git clone https://github.com/once-ere/Dirac_claude.git
py -3 -m venv "$HOME\dirac-book-env"
Set-ExecutionPolicy -ExecutionPolicy RemoteSigned -Scope Process -Force
& "$HOME\dirac-book-env\Scripts\Activate.ps1"
python -m pip install --upgrade pip
python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
```

The line with ‘Set-ExecutionPolicy‘ allows PowerShell to run the activation script in this one window only; it changes nothing permanently.

macOS (zsh):

```
cd ~
git clone https://github.com/once-ere/Dirac_claude.git
python3 -m venv ~/dirac-book-env
source ~/dirac-book-env/bin/activate
python -m pip install --upgrade pip
python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
```

Linux (bash):

```
cd ~
git clone https://github.com/once-ere/Dirac_claude.git
python3 -m venv ~/dirac-book-env
source ~/dirac-book-env/bin/activate
python -m pip install --upgrade pip
python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
```

Step 4. In every new terminal: activate the environment and go into the repository folder.

Every later step starts in the repository folder with the environment active. Run these lines whenever you open a new terminal (they do no harm if the environment is already active):

Windows (PowerShell):

```
Set-ExecutionPolicy -ExecutionPolicy RemoteSigned -Scope Process -Force
& "$HOME\dirac-book-env\Scripts\Activate.ps1"
cd "$HOME\Dirac_claude"
```

macOS (zsh) and Linux (bash):

```
source ~/dirac-book-env/bin/activate
cd ~/Dirac_claude
```

Step 5. Run the notebook in JupyterLab.

In the repository folder, with the environment active, run these two lines (the first one goes into the folder of the notebooks):

Windows, macOS and Linux:

```
cd Revision/textbook/notebooks
jupyter lab 15e_shooting_by_hand.ipynb
```

JupyterLab opens in your web browser and shows the notebook (if no browser window opens, copy the address that starts with ‘http://localhost:8888/lab‘ from the terminal into the address bar of your browser). The name at the top right of the notebook must read Python 3 (ipykernel). Choose the menu Run > Run All Cells. While a cell runs, the label to its left shows ‘[*]‘; when it has finished, the label shows a number. The notebook has finished when the last code cell shows a number; this takes about 25 seconds on a typical laptop. Scroll to the end and compare the last printed lines with the lines in the step "What the notebook writes and what you must see" below. To keep the results, save the notebook (menu File > Save Notebook). To stop JupyterLab, choose the menu File > Shut Down, or press Ctrl+C twice in the terminal.

Step 6. Or run the notebook without a browser (headless).

In the repository folder, with the environment active, run:

Windows, macOS and Linux:

```
cd Revision/textbook/notebooks
jupyter nbconvert --to notebook --execute --inplace 15e_shooting_by_hand.ipynb
```

This runs every cell from the top to the bottom and saves the results into the notebook file. A failed check stops it with an error message that contains AssertionError and the name of the check. If the command ends with a line that starts with ‘[NbConvertApp] Writing‘ and shows no error, every check passed; open the notebook with ‘jupyter lab 15e_shooting_by_hand.ipynb‘ (in the same folder, without running the cells again) to read the printed lines and see the figures.

Step 7. What the notebook writes and what you must see.

The notebook writes (or overwrites) these files:

- ‘Revision/textbook/figures/15e.captions.json‘
- ‘Revision/textbook/figures/15e_1_phase_function.png‘

- ‘Revision/textbook/figures/15e_2_orbitals.png‘
- ‘Revision/textbook/figures/15e_3_rk4_convergence.png‘
- ‘Revision/textbook/figures/15e_4_brane_band.png‘
- ‘Revision/textbook/figures/15e_5_scf_mixing.png‘
- ‘Revision/textbook/figures/15e_6_n8_potentials.png‘

It changes no other file of the repository; running it headless or saving it in JupyterLab also rewrites the notebook file itself. It does not use the internet while it runs. The files it writes are the same files that are stored in the repository (on another computer a figure may differ in a few bytes, which is harmless). To get the stored versions back, run this command in the repository folder (it also undoes every change you made yourself in the folder Revision/textbook):

Windows, macOS and Linux:

```
git checkout -- Revision/textbook
```

Every check of the notebook prints a line that starts with PASS. At the end of the notebook (the output of its last code cell) you must see exactly these lines:

```
PASS every figure file of this notebook exists
ALL 18 CHECKS PASSED (notebook 15e)
```

and the notebook must show 6 figures below the cells that draw them.

Step 8. If something goes wrong.

- "ModuleNotFoundError: No module named ..." in the notebook: JupyterLab was started without the environment. Stop it (menu File > Shut Down), do Step 4, and start it again. If the error remains, another Python installation has registered its own kernel called python3; with the environment active, run the following command and start JupyterLab again:

  ```
  python -m ipykernel install --user --name python3
  ```

- "FileNotFoundError: The repository folder was not found": the notebook was opened from a copy outside the repository. Open the file ‘Revision/textbook/notebooks/15e_shooting_by_hand.ipynb‘ inside the folder Dirac_claude.
- "fatal: destination path ’Dirac_claude’ already exists" in Step 3: the repository was downloaded before; skip the line with ‘git clone‘.
- Windows: "running scripts is disabled on this system": run the line with ‘Set-ExecutionPolicy‘ and then the activation line again. "py is not recognized": use ‘python‘ instead of ‘py -3‘; "python is not recognized": install Python again and tick "Add python.exe to PATH".
- Linux: "ensurepip is not available" when the environment is created: run ‘sudo apt install python3-venv‘ and repeat Step 3.
- "jupyter is not recognized" or "command not found: jupyter": the environment is not active; do Step 4. If the environment is active and the message stays, the programs jupyter-lab and jupyter-nbconvert are not in the folders where the terminal looks for programs (‘python -m jupyter‘ does not help then: it has to find the same programs). Start them through Python itself, in the folder of the notebook: the first command below does what ‘jupyter lab‘ does, the second what the headless command does:

```
      python -m jupyterlab 15e_shooting_by_hand.ipynb
      python -m nbconvert --execute --inplace 15e_shooting_by_hand.ipynb

- Windows: the headless run prints a RuntimeWarning that mentions the "Proactor event
  loop" and zmq: this is a message of the package pyzmq, not an error; the run continues
  normally.
- A red box with "Matplotlib is building the font cache; this may take a moment." in the
  first run after the installation: this is a message, not an error; the run continues
  and the message does not come again.
- An AssertionError names a check that failed: choose the menu Kernel > Restart Kernel
  and Run All Cells; if it fails again, install the packages again with the pip commands
  of Step 3, because a different package version can change the last digits of a result.

The first code cell below (the set-up cell) repeats these instructions as comments; then
it imports the packages, finds the repository folder and defines the helpers
‘save_figure‘ (saves a figure and shows it), ‘check‘ (stops with an AssertionError when a
check fails, prints a PASS line when it passes), ‘report‘ (prints a key number as a
RESULT line) and ‘all_checks_passed‘ (prints the last line).
```

In [1]:

```
# HOW TO RUN NOTEBOOK 15e (the complete instructions)
#
# STEP 1. WHAT THIS NOTEBOOK DOES AND WHAT IT NEEDS.
#
# Notebook 15e (The solver's method by hand: shooting, Pruefer count and Anderson mixing)
# is the file Revision/textbook/notebooks/15e_shooting_by_hand.ipynb of the repository
# Dirac_claude. It re-implements in plain Python the numerical method of the Rust
# Kohn-Sham solver (fourth-order Runge-Kutta shooting in the hidden coordinate, the
# Pruefer angle that labels every level, a safeguarded Newton root, the normalisation of
# the orbitals, and the self-consistent loop with Anderson mixing), and uses it to
# reproduce the solver's exact free spectra, its convergence order, the slope of the
# brane band and the interacting ground states of N = 8 particles from the committed
# Revision record. It needs a computer with Windows 11, macOS or Linux, an internet
# connection for the installation, the program Git, and Python 3.12 or newer (the
# notebooks were built with Python 3.14.5) with these packages at exactly these versions:
# numpy 2.4.6, sympy 1.14.0, mpmath 1.3.0, matplotlib 3.11.0, jupyterlab 4.4.10, nbformat
# 5.10.4, nbclient 0.10.2, ipykernel 7.1.0 and nbconvert 7.16.6. The notebook itself
# imports numpy and matplotlib; the other packages run Jupyter, the program that shows
# and runs notebooks. It does not need Rust.
#
# STEP 2. INSTALL GIT AND PYTHON (ONCE PER COMPUTER).
#
# A terminal is the window in which you type commands: on Windows the app Windows
# PowerShell (or Terminal), on macOS the app Terminal (it runs the shell zsh), on Linux
# any terminal (it runs the shell bash). Type every command of this section into a
# terminal exactly as printed, one line at a time, and press Enter after each line.
#
# Windows: download Git from https://git-scm.com/download/win and install it with the
# default choices. Download Python from https://www.python.org/downloads/ and run the
# installer; in its first window tick the box "Add python.exe to PATH" before you click
# "Install Now".
#
```

```
# macOS: download Python from https://www.python.org/downloads/ and run the installer.
# Then open the app Terminal and run this command, which installs Git and the compiler
# tools:
#
# macOS (zsh):
#     xcode-select --install
#
# Linux (Debian or Ubuntu; other distributions have packages of the same names): run
# these two commands:
#
# Linux (bash):
#     sudo apt update
#     sudo apt install git python3 python3-venv
#
# Then close the terminal and open a NEW one (a terminal opened before the installation
# does not know the new programs), and check the version of Python; it must print 3.12 or
# a higher number:
#
# Windows (PowerShell):
#     py -3 --version
#
# macOS (zsh) and Linux (bash):
#     python3 --version
#
# If an older Linux prints a lower number (Ubuntu 22.04 has Python 3.10), install Python
# 3.12 with the following three commands, and in Step 3 type python3.12 instead of
# python3 in the command that creates the environment:
#
# Linux (bash), only when the version is too low:
#     sudo add-apt-repository ppa:deadsnakes/ppa
#     sudo apt update
#     sudo apt install python3.12 python3.12-venv
#
# STEP 3. GET THE REPOSITORY AND INSTALL THE PACKAGES (ONCE PER COMPUTER).
#
# The commands below download the repository (a few hundred megabytes; the folder then
# needs up to about 1 GB of disk space) into the folder Dirac_claude inside your home
# folder, create a private Python environment in the folder dirac-book-env inside your
# home folder (a private environment is a folder with its own copy of Python and of the
# packages, so that nothing else on your computer is changed), activate it (from then on
# the commands python and jupyter typed in this terminal are those of the environment,
# and the prompt starts with (dirac-book-env)), and install the packages at the pinned
# versions (this downloads about 90 MB and takes a few minutes; the environment takes
# about 400 MB of disk space). If you have done this step before, for this or for another
# notebook, skip it and go to Step 4; to get the newest version of the repository, run
# git pull in the repository folder after Step 4.
#
# Windows (PowerShell):
#     cd $HOME
#     git clone https://github.com/once-ere/Dirac_claude.git
#     py -3 -m venv "$HOME\dirac-book-env"
#     Set-ExecutionPolicy -ExecutionPolicy RemoteSigned -Scope Process -Force
#     & "$HOME\dirac-book-env\Scripts\Activate.ps1"
#     python -m pip install --upgrade pip
```

```
#     python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
#     python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
#     python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
#
# The line with Set-ExecutionPolicy allows PowerShell to run the activation script in
# this one window only; it changes nothing permanently.
#
# macOS (zsh):
#     cd ~
#     git clone https://github.com/once-ere/Dirac_claude.git
#     python3 -m venv ~/dirac-book-env
#     source ~/dirac-book-env/bin/activate
#     python -m pip install --upgrade pip
#     python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
#     python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
#     python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
#
# Linux (bash):
#     cd ~
#     git clone https://github.com/once-ere/Dirac_claude.git
#     python3 -m venv ~/dirac-book-env
#     source ~/dirac-book-env/bin/activate
#     python -m pip install --upgrade pip
#     python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
#     python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
#     python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
#
# STEP 4. IN EVERY NEW TERMINAL: ACTIVATE THE ENVIRONMENT AND GO INTO THE REPOSITORY
# FOLDER.
#
# Every later step starts in the repository folder with the environment active. Run these
# lines whenever you open a new terminal (they do no harm if the environment is already
# active):
#
# Windows (PowerShell):
#     Set-ExecutionPolicy -ExecutionPolicy RemoteSigned -Scope Process -Force
#     & "$HOME\dirac-book-env\Scripts\Activate.ps1"
#     cd "$HOME\Dirac_claude"
#
# macOS (zsh) and Linux (bash):
#     source ~/dirac-book-env/bin/activate
#     cd ~/Dirac_claude
#
# STEP 5. RUN THE NOTEBOOK IN JUPYTERLAB.
#
# In the repository folder, with the environment active, run these two lines (the first
# one goes into the folder of the notebooks):
#
# Windows, macOS and Linux:
#     cd Revision/textbook/notebooks
#     jupyter lab 15e_shooting_by_hand.ipynb
#
# JupyterLab opens in your web browser and shows the notebook (if no browser window
# opens, copy the address that starts with http://localhost:8888/lab from the terminal
```

```
# into the address bar of your browser). The name at the top right of the notebook must
# read Python 3 (ipykernel). Choose the menu Run > Run All Cells. While a cell runs, the
# label to its left shows [*]; when it has finished, the label shows a number. The
# notebook has finished when the last code cell shows a number; this takes about 25
# seconds on a typical laptop. Scroll to the end and compare the last printed lines with
# the lines in the step "What the notebook writes and what you must see" below. To keep
# the results, save the notebook (menu File > Save Notebook). To stop JupyterLab, choose
# the menu File > Shut Down, or press Ctrl+C twice in the terminal.
#
# STEP 6. OR RUN THE NOTEBOOK WITHOUT A BROWSER (HEADLESS).
#
# In the repository folder, with the environment active, run:
#
# Windows, macOS and Linux:
#     cd Revision/textbook/notebooks
#     jupyter nbconvert --to notebook --execute --inplace 15e_shooting_by_hand.ipynb
#
# This runs every cell from the top to the bottom and saves the results into the notebook
# file. A failed check stops it with an error message that contains AssertionError and
# the name of the check. If the command ends with a line that starts with [NbConvertApp]
# Writing and shows no error, every check passed; open the notebook with jupyter lab
# 15e_shooting_by_hand.ipynb (in the same folder, without running the cells again) to
# read the printed lines and see the figures.
#
# STEP 7. WHAT THE NOTEBOOK WRITES AND WHAT YOU MUST SEE.
#
# The notebook writes (or overwrites) these files:
#
# - Revision/textbook/figures/15e.captions.json
# - Revision/textbook/figures/15e_1_phase_function.png
# - Revision/textbook/figures/15e_2_orbitals.png
# - Revision/textbook/figures/15e_3_rk4_convergence.png
# - Revision/textbook/figures/15e_4_brane_band.png
# - Revision/textbook/figures/15e_5_scf_mixing.png
# - Revision/textbook/figures/15e_6_n8_potentials.png
#
# It changes no other file of the repository; running it headless or saving it in
# JupyterLab also rewrites the notebook file itself. It does not use the internet while
# it runs. The files it writes are the same files that are stored in the repository (on
# another computer a figure may differ in a few bytes, which is harmless). To get the
# stored versions back, run this command in the repository folder (it also undoes every
# change you made yourself in the folder Revision/textbook):
#
# Windows, macOS and Linux:
#     git checkout -- Revision/textbook
#
# Every check of the notebook prints a line that starts with PASS. At the end of the
# notebook (the output of its last code cell) you must see exactly these lines:
#
#     PASS every figure file of this notebook exists
#     ALL 18 CHECKS PASSED (notebook 15e)
#
# and the notebook must show 6 figures below the cells that draw them.
#
```

```
# STEP 8. IF SOMETHING GOES WRONG.
#
# - "ModuleNotFoundError: No module named ..." in the notebook: JupyterLab was started
#   without the environment. Stop it (menu File > Shut Down), do Step 4, and start it
#   again. If the error remains, another Python installation has registered its own
#   kernel called python3; with the environment active, run the following command and
#   start JupyterLab again:
#     python -m ipykernel install --user --name python3
# - "FileNotFoundError: The repository folder was not found": the notebook was opened
#   from a copy outside the repository. Open the file
#   Revision/textbook/notebooks/15e_shooting_by_hand.ipynb inside the folder
#   Dirac_claude.
# - "fatal: destination path 'Dirac_claude' already exists" in Step 3: the repository was
#   downloaded before; skip the line with git clone.
# - Windows: "running scripts is disabled on this system": run the line with
#   Set-ExecutionPolicy and then the activation line again. "py is not recognized": use
#   python instead of py -3; "python is not recognized": install Python again and tick
#   "Add python.exe to PATH".
# - Linux: "ensurepip is not available" when the environment is created: run sudo apt
#   install python3-venv and repeat Step 3.
# - "jupyter is not recognized" or "command not found: jupyter": the environment is not
#   active; do Step 4. If the environment is active and the message stays, the programs
#   jupyter-lab and jupyter-nbconvert are not in the folders where the terminal looks for
#   programs (python -m jupyter does not help then: it has to find the same programs).
#   Start them through Python itself, in the folder of the notebook: the first command
#   below does what jupyter lab does, the second what the headless command does:
#     python -m jupyterlab 15e_shooting_by_hand.ipynb
#     python -m nbconvert --execute --inplace 15e_shooting_by_hand.ipynb
# - Windows: the headless run prints a RuntimeWarning that mentions the "Proactor event
#   loop" and zmq: this is a message of the package pyzmq, not an error; the run
#   continues normally.
# - A red box with "Matplotlib is building the font cache; this may take a moment." in
#   the first run after the installation: this is a message, not an error; the run
#   continues and the message does not come again.
# - An AssertionError names a check that failed: choose the menu Kernel > Restart Kernel
#   and Run All Cells; if it fails again, install the packages again with the pip
#   commands of Step 3, because a different package version can change the last digits of
#   a result.

## 3. The words used in this notebook

- **Orbital**: a one-particle wave function; here a pair of real functions $a(y)$,
  $b(y)$ of the hidden coordinate $y$.
- **Ordinary differential equation (ODE)**: an equation for functions of one
  variable that contains their derivatives. Given the values at one point (the
  **initial values**) it fixes the functions everywhere.
- **RK4** (the classical fourth-order Runge-Kutta method): a recipe that advances
  the solution of an ODE by one **step** $h$ using four evaluations of the
  derivatives; its error falls like $h^4$.
- **Shooting**: guess an energy $\varepsilon$, start the orbital at one end with
  the boundary condition of that end, integrate to the other end, and change
  $\varepsilon$ until the boundary condition there holds too.
- **Pruefer angle**: the angle $\theta$ of the point $(a, b)$ seen from the origin,
  $a = r\cos\theta$, $b = r\sin\theta$, followed continuously (it may grow beyond
  $2\pi$).
- **Phase function** $\Phi(\varepsilon)$: $j$ times the Pruefer angle at the brane.
  It increases strictly with $\varepsilon$.
- **Label** $l$: the whole number that says which crossing of $\Phi$ with the
  targets $l\pi$ (even parity) or $\pi/2 + l\pi$ (odd parity) a level is.
- **Root**: a value where a function is zero. **Newton's method** improves a guess
  $x$ to $x - F(x)/F'(x)$. A **bracket** is an interval known to contain the root;
  **bisection** halves it.
- **Normalisation**: multiplying an orbital by a number so that
  $\int_{-L}^{0} (a^2 + b^2)\,dy = 1$.
- **Simpson's rule**: $\int f\,dy \approx \tfrac{h}{6}[f_0 + 4 f_{1/2} + 2 f_1 +
  4 f_{3/2} + \dots + f_G]$ on the step ends and midpoints of $G$ steps.
- **Cubic Hermite interpolation**: the value in the middle of a step from the values
  and the derivatives at its two ends.
- **Self-consistency, residual, mixing**: the potentials made from the orbitals must
  equal the potentials that made the orbitals. The residual is the largest change
  in one iteration. **Linear mixing** moves a fraction $\beta$ of the way toward the
  new potential; **Anderson mixing** combines the last few iterations so that their
  residuals cancel as far as possible.
```

## 4. The physical and mathematical situation

The author's metric has 3-space $x_1, x_2, x_3$ (scale factor $e^{a_4}\sin^{1/6} z$),
the time $x_4$, three extra times $x_5, x_6, x_7$ that deflate exponentially (scale
factor $e^{-a_4}\sin^{1/6} z$) and the hidden direction $x_0$, with $z = 6 H x_0$.
In the hidden coordinate $y = \ln(\sin z)/(6H)$, from the tip $y = -L$ to the brane
$y = 0$, the Kohn-Sham equation of dirac16complex reduces exactly (Revision record
Revision/kohn_sham/ks-theory.json) to eight $2 \times 2$ blocks. With the orbital
written as $\chi = (a, i\,b)$, $a$ and $b$ real, a block of type $j = \pm 1$ at the
3-momentum $k$ is the real system
```

$$a' = M a - (\kappa k + j(\varepsilon - v))\,b, \qquad
b' = (j(\varepsilon - v) - \kappa k)\,a - M b, \qquad \kappa = e^{-Hy - a_{4,0}},$$

with the effective mass $M(y)$ and potential $v(y)$. Boundary conditions: at the tip $b(-L) = 0$ (chosen); at the brane $b(0) = 0$ for even and $a(0) = 0$ for odd parity (the Z2 mirror, ASSUMED).

The Pruefer angle. Write $a = r\cos\theta$, $b = r\sin\theta$. Then $a b' - b a' = r^2 \theta'$. Inserting the system:

$$a b' - b a' = j(\varepsilon - v)(a^2 + b^2) - \kappa k (a^2 - b^2) - 2 M a b,$$

because the terms $-M a b$ (from $a b'$) and $-M a b$ (from $-b a'$) add, the terms with κk give $-\kappa k a^2 + \kappa k b^2$, and the terms with $j(\varepsilon - v)$ give $j(\varepsilon - v)(a^2 + b^2)$. Dividing by r^2 and using $a^2 - b^2 = r^2\cos 2\theta$ and $2ab = r^2\sin 2\theta$:

$$\theta' = j(\varepsilon - v) - \kappa k \cos 2\theta - M \sin 2\theta .$$

At the tip $\theta(-L) = 0$ (because $b = 0$ there). Write $\psi = j\theta$. Multiplying the angle equation by j and using $j^2 = 1$, $\cos(2j\psi) = \cos 2\psi$ and $\sin(2j\psi) = j\sin 2\psi$ gives

$$\psi' = \varepsilon + G(y, \psi), \qquad
G(y, \psi) = -v - j\kappa k \cos 2\psi - M \sin 2\psi ,$$

and G does not contain ε. The **phase function** $\Phi(\varepsilon) = j\,\theta(0) = \psi(0)$ increases strictly with ε, by a comparison of two energies $\varepsilon_1 < \varepsilon_2$: let ψ_1, ψ_2 be their angles (both 0 at the tip) and $D = \psi_2 - \psi_1$. At the tip $D = 0$ and $D' = \varepsilon_2 - \varepsilon_1 > 0$, so $D > 0$ just after the tip. If D came back to 0 at a first point y_1, it would arrive there from positive values, so $D'(y_1) \le 0$; but at y_1 the two angles are equal, the two G terms cancel and $D'(y_1) = \varepsilon_2 - \varepsilon_1 > 0$. This contradiction shows $D(0) > 0$, that is $\Phi(\varepsilon_2) > \Phi(\varepsilon_1)$. (The exact derivative $d\Phi/d\varepsilon = \int r^2 dy / r(0)^2 > 0$, which section 6 uses for Newton's method, says the same.) Φ also runs from $-\infty$ to $+\infty$: if $|v|$, κk and $|M|$ are at most C_0 on the interval, then $|G| \le 3C_0$, and integrating ψ' over the length L gives $(\varepsilon - 3C_0)L \le \Phi(\varepsilon) \le (\varepsilon + 3C_0)L$, so $\Phi(\varepsilon) \approx \varepsilon L$ for large $|\varepsilon|$. Even parity, $b(0) = 0$, means $\theta(0)$ is a whole multiple of π; odd parity, $a(0) = 0$, means $\theta(0) = \pi/2 + $ a multiple of π. Because Φ increases strictly, each target $l\pi$ (even) or $\pi/2 + l\pi$ (odd) is reached at exactly one energy: **every level has its own whole number l, and no level can be missed** (the oscillation theorem).

Exact levels at $k = 0$ with constant $M = m$ and $v = 0$ (Revision record ks-theory.json, boundaryConditions.exactK0Spectra): even parity: $\varepsilon = 0$ with the zero mode $(a, b) = (e^{My}, 0)$, and $\varepsilon = \pm\sqrt{M^2 + (n\pi/L)^2}$, $n = 1, 2, \dots$; odd parity: $\varepsilon = \pm\sqrt{M^2 + p^2}$ with $\tan(pL) = -p/M$.

The self-consistent problem for $N = 8$. Eight particles fill the eight zero

```
modes at $k = 0$ (four orbitals for each $j$). Their proper densities are
$n = \sum w\,g\,f\,P\,(a^2 + b^2)$ and $S = \sum w\,g\,f\,P\,j\,2ab$ with
$P = e^{-6Hy}/\mathrm{Vol}_7$, $w = 1/2$, $g = 4$, $f = 1$; the potentials are
$M = m + \tfrac{15}{16}\lambda S$ and $v = -\tfrac{1}{16}\lambda n$; the energy is
$E_{KS} = \sum g f \varepsilon - 2\,\mathrm{Vol}_7 \int e^{6Hy} e_{int}\,dy$ with
$e_{int} = \lambda(\tfrac{15}{32}S^2 - \tfrac{1}{32}n^2)$. Units $H = m = 1$, $L = 3$,
$\Delta k = 0.25$, $\mathrm{Vol}_7 = (2\pi/\Delta k)^3$.

The history $a_4 = A H x_4$ is a PRESCRIBED BACKGROUND; the states are instantaneous
states at a slice $a_{4,0}$, which enters only through $\kappa$.
```

Text cell:

```
## 5. The grid

The solver integrates with $G = 900$ RK4 steps of length $h = L/G$ from $y = -L$ to
$y = 0$. Every RK4 step needs the potentials at its two ends and at its midpoint, so
the potentials live on the **fine grid** of the $2G + 1$ step ends and midpoints.
The next cell builds this grid exactly as the solver does: the coordinates $y_f$,
the factors $e^{-Hy}$ (for $\kappa$) and $e^{6Hy}$ (the proper volume), and the
Simpson weights. The check: Simpson's rule integrates $e^{y}$ from $-3$ to $0$ to
$1 - e^{-3}$ within $10^{-13}$.
```

## 6. Shooting: one integration from the tip to the brane

The next cell is the heart of the method. `rhs` is the right-hand side $(a', b')$ of
the block equation. `shoot` starts at the tip with $(a, b) = (1, 0)$ (this satisfies
$b(-L) = 0$), makes $G$ RK4 steps to the brane, and follows the Pruefer angle: after
each step it computes the angle of the new point with `atan2` and adds the change of
angle (brought into $(-\pi, \pi]$) to $\theta$, so $\theta$ is followed continuously.
It also adds up $\int r^2\,dy$ with the trapezoid rule on the step ends,
$\tfrac{h}{2}(r_i^2 + r_{i+1}^2)$ per step, exactly as the solver does, for the
derivative $d\Phi/d\varepsilon = \int r^2 dy / r(0)^2$, which Newton's method needs.
When asked (`store=True`) it keeps the values at the step ends. The potentials
`mass` and `pot` are lists of $M$ and $v$ on the fine grid.
```

In [3]:

```
def rhs(m_y, kk, je, a, b):

```

Text cell:

```
Why $d\Phi/d\varepsilon = \int r^2 dy / r(0)^2$, line by line. Call
$u = \partial\theta/\partial\varepsilon$. (1) Differentiating the angle equation
$\theta' = j(\varepsilon - v) - \kappa k\cos 2\theta - M\sin 2\theta$ with respect
to $\varepsilon$ gives $u' = j + (2\kappa k\sin 2\theta - 2M\cos 2\theta)\,u$ (chain
rule), with $u(-L) = 0$ because $\theta(-L) = 0$ for every $\varepsilon$.
(2) The length $r$ obeys $(\ln r)' = (a a' + b b')/r^2 = M\cos 2\theta -
\kappa k\sin 2\theta$ (insert the system; the terms with $j(\varepsilon - v)$
cancel). (3) So $u' = j - 2(\ln r)'\,u$, and therefore $(r^2 u)' = r^2 u' + 2 r r' u
= j r^2$ (product rule). (4) Integrating from the tip to the brane:
$r(0)^2 u(0) = j\int r^2 dy$. (5) Since $\Phi = j\theta(0)$ and $j^2 = 1$,
$d\Phi/d\varepsilon = j u(0) = \int r^2 dy / r(0)^2 > 0$. This is the strict
increase of $\Phi$ in a formula, and the derivative that Newton's method uses.
```

Text cell:

```
## 7. The phase function and the levels it labels

The next cell evaluates $\Phi(\varepsilon)$ at 401 energies from $-4$ to $4$ for
$k = 0$, $j = +1$, without interaction, and draws $\Phi/\pi$. The levels of even
parity are where $\Phi/\pi$ crosses a whole number, those of odd parity where it
crosses a whole number plus one half. The check confirms that $\Phi$ increases at
every one of the 400 steps.
```

In [4]:

## 8. Finding a level: Newton's method inside a bracket

The next cell finds the level with label $l$: the root of $\Phi(\varepsilon) - t_l$
with the target $t_l = l\pi$ (even) or $\pi/2 + l\pi$ (odd). It is the solver's
'find_level', step for step: from a guess it walks with doubling steps (up if
$\Phi < t_l$, down otherwise) until the sign of $\Phi - t_l$ changes (a bracket),
then it takes Newton steps $\varepsilon \to \varepsilon - (\Phi - t_l)/\Phi'$ and
falls back to bisection whenever a Newton step would leave the bracket or the
previous step did not halve the error. It stops when the bracket is shorter than
$10^{-13}$, or when a Newton step moved the energy by at most $10^{-13}$ (Newton's
method approaches the root from one side, so the bracket itself need not shrink).
```

In [5]:

```
def target(parity, label):
    """Phi of the level with this label: l pi (even) or pi/2 + l pi (odd)."""
```

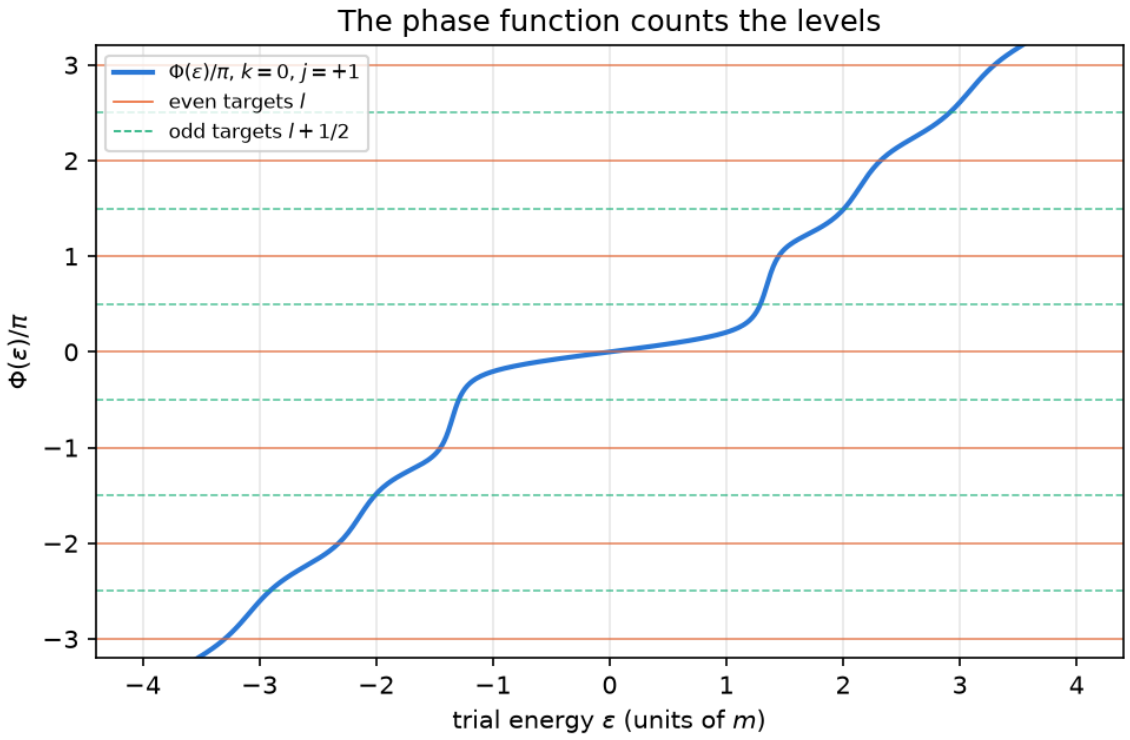

Figure 405: The phase function $\Phi(\varepsilon)/\pi$ (vertical axis) of the free block $j = +1$ at $k = 0$ against the trial energy ε (horizontal axis, units of m). It rises steadily; it crosses a solid line (a whole number l) at each level of even parity and a dashed line ($l + 1/2$) at each level of odd parity. The flat part around $\varepsilon = 0$ is the gap of the free field, with the zero mode at $\Phi = 0$. (Notebook 15e, figure 1.)

the odd ones by bisection on $M\sin(pL) + p\cos(pL) = 0$, which is $\tan(pL) = -p/M$
multiplied by $M\cos(pL)$), finds the labels $-3$ to $5$ of both parities by
shooting, and compares. It also compares with the solver's own numerical values in
the record file `spectrum/free-k0-analytic.csv`: the same method on the same grid
must give the same numbers to the root tolerance.

## 9. Orbitals: the values in the middle of the steps, and the normalisation

RK4 gives the orbital at the step ends. The densities (and the potentials) are
needed on the whole fine grid, so the solver fills in each midpoint by **cubic
Hermite interpolation**: with the values $u_0, u_1$ and derivatives $u'_0, u'_1$ at
```

```
the two ends of a step of length $h$, the midpoint value is
$\tfrac12(u_0 + u_1) + \tfrac{h}{8}(u'_0 - u'_1)$ (exact for every cubic polynomial;
the derivatives come from the equation itself). Then the orbital is normalised with
Simpson's rule. The next cell defines this and draws three orbitals: the zero mode,
the first even bulk level at $k = 0$, and the brane-band level at $k = 0.5$ (the
shell $n_2 = 4$). The check compares the zero mode with its exact form
$a = \sqrt{2M/(1 - e^{-2ML})}\,e^{My}$, $b = 0$.
```

In [7]:

```
def orbital(eps, k, j, a4, mass, pot, grid=GRID):
    """The normalised orbital (a, b) on the fine grid (two numpy arrays)."""

## 10. How accurate is RK4? The order 4

The error of RK4 falls like $h^4$: halving the step divides it by $2^4 = 16$. The
next cell finds the even levels with the labels 2 and 3 at $k = 0$ (exact values
$\sqrt{1 + (2\pi/3)^2}$ and $\sqrt{1 + \pi^2}$) on grids of 100, 200, 400 and 800
steps, prints the errors and their ratios, and draws the errors against the step on
logarithmic axes, where $h^4$ is a straight line of slope 4. The solver measured the
ratio 16.00 between its canonical and refined runs (Revision record
ks-rust-determinism.json, check ‘refined_free_spectra_convergence_order‘).
```

In [8]:

## 11. The brane band and the deflating history

For $k > 0$ the lowest even level of $j = +1$ (label 0) is the **brane band**: an
orbital bound to the brane whose energy grows with $k$. The record gives its slope
at $k = 0$ in closed form (Revision/kohn_sham/ks-theory.json, checksNumeric):
$c = \frac{2M}{2M - H}\,\frac{1 - e^{-(2M - H)L}}{1 - e^{-2ML}} = 1.90514825360$ for
$M = H = 1$, $L = 3$, times $e^{-a_{4,0}}$ at the slice $a_{4,0}$. The next cell
computes the band at 41 momenta from 0 to 2 at the slices $a_{4,0} = 0$, $1$, $2$,
and measures the slope at $k = 0$ from $s(k) = \varepsilon(k)/k$ at
$k = 10^{-4}$ and $2 \times 10^{-4}$. Without interaction the band is an **odd**
function of $k$: the two exact symmetries of the block Hamiltonian (Revision record
ks-theory.json, blockEquation.typeRelation), $\sigma_3 h_j(k) \sigma_3 = h_{-j}(-k)$
and $h_{-1} = -h_{+1}$ (for $v = 0$), give together that $-\varepsilon$ is a level
of $h_{+1}(-k)$ whenever $\varepsilon$ is a level of $h_{+1}(k)$. The labels go
along: the first map changes the signs of $b$ and $j$, so $\Phi = j\theta(0)$ and
every label stay the same; the second keeps $(a, b)$ and changes the signs of $j$
and $\varepsilon$, so $\Phi \to -\Phi$ and the even label $l$ goes to $-l$
(Revision/kohn_sham/reports/ks-rust-solver.json, check
free_block_type_symmetries). The band, the even label 0, therefore goes to the
even label 0: $\varepsilon(-k) = -\varepsilon(k)$ for the band itself. So
$\varepsilon(k) = c k - d k^3 + \dots$ and $s(k) = c - d k^2 + \dots$: the error of
$s$ grows fourfold when $k$ doubles, and the **Richardson extrapolation**
$\tfrac{1}{3}(4 s(k) - s(2k))$ removes it (the $k^2$ terms cancel:
$4(c - dk^2) - (c - 4dk^2) = 3c$). The cell prints the measured factor. Finally it
checks the **rescaling identity**: the level at the slice $a_{4,0}$ equals the
level at the slice $0$ with the momentum $k e^{-a_{4,0}}$, because $a_{4,0}$ enters
only through $\kappa k$.

## 12. The self-consistent loop for N = 8

Now the interaction. The eight particles of the state $N = 8$ fill the zero modes of
```

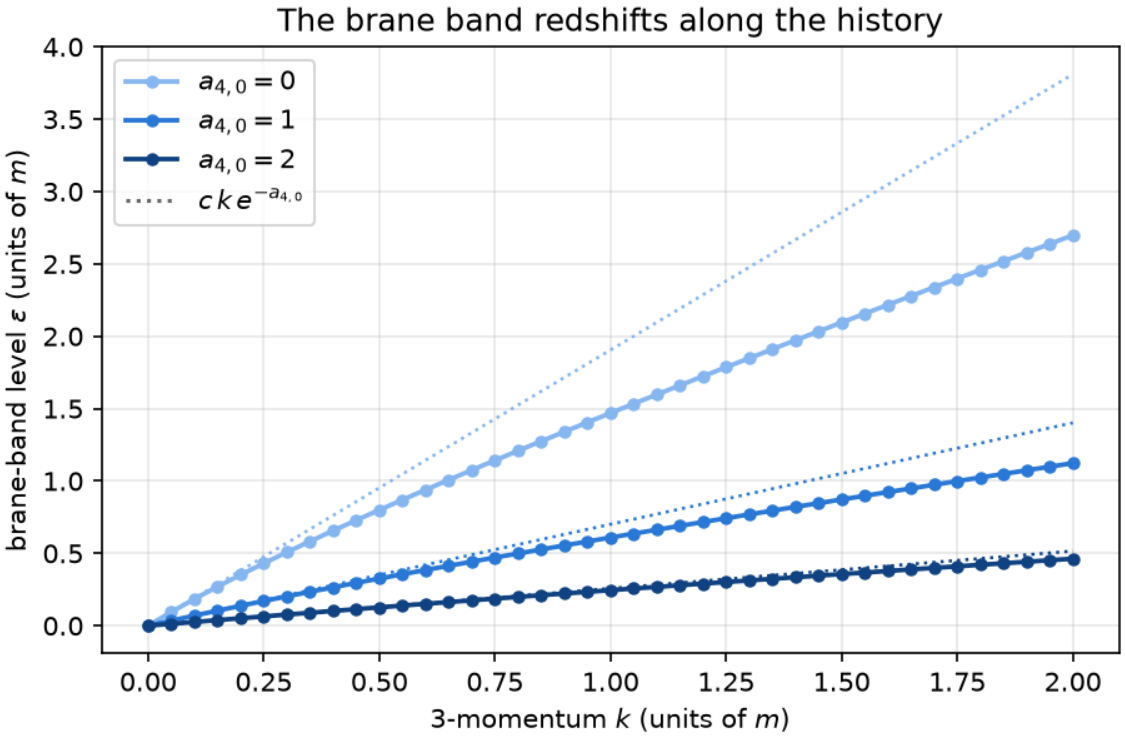

Figure 408: The brane-band level $\varepsilon(k)$ (vertical axis, units of m) against the 3-momentum k (horizontal axis, units of m) at the slices $a_{4,0} = 0$, 1, 2 (light to dark blue); the dotted lines are the tangents $c\,k\,e^{-a_{4,0}}$ at $k = 0$ with $c = 1.9051482536$. Along the deflating history the whole band is squeezed toward $\varepsilon = 0$: each curve is the previous one with the momentum axis stretched by $e = 2.718$. (Notebook 15e, figure 4.)

both block types $j = \pm 1$ at $k = 0$ (four orbitals each). The next cell defines one **iteration**: from the current potentials ($M - m$ and v on the fine grid, one vector `x` of length 2×1801) it finds the two occupied levels (label 0, even parity, $k = 0$, $j = \pm 1$), builds their normalised orbitals, the proper densities n and S, the output potentials, the residual (largest difference between output and input) and the energy E_{KS}. It also defines **Anderson mixing** exactly as the solver does: it keeps the last six inputs x_i and residuals r_i, finds the weights c_i with $\sum c_i = 1$ that make $\sum c_i r_i$ as small as possible (a small linear system), and takes $\sum c_i (x_i + \beta r_i)$ with $\beta = 0.4$ as the next input; its history is cleared when a residual grows tenfold.

## 13. Why Anderson mixing? A comparison with linear mixing

The next cell solves the same state again with **linear mixing** (the next input is
$x + 0.4\,r$) and draws both residual histories together with the solver's recorded
one. Linear mixing reaches the same state but needs several times more iterations;
the solver's record and this notebook's Anderson run lie on top of each other.
```

In [12]:

```

```

Text cell:

```
## 14. All four couplings, and an exact symmetry

The next cell solves $N = 8$ for $+\lambda_1$, $-\lambda_1$, $+\lambda_2$,
$-\lambda_2$, compares the energies and occupied levels with the record, and computes
the lowest empty level (the LUMO: the brane band at $k = 0.25$ in the final
potentials) for $+\lambda_1$. Then it checks an **exact symmetry** of this state:
changing the sign of $\lambda$ changes the sign of the energy. The reason, line by
line. (1) At $k = 0$ the real system of block $j$ is $a' = M a - j(\varepsilon -
v)\,b$, $b' = j(\varepsilon - v)\,a - M b$. (2) Put $\tilde a = a$, $\tilde b = -b$,
$\tilde\varepsilon = -\varepsilon$, $\tilde v = -v$, the same $M$ and the same $j$;
then $\tilde\varepsilon - \tilde v = -(\varepsilon - v)$, and the two equations
become $\tilde a' = M\tilde a - j(\tilde\varepsilon - \tilde v)\,\tilde b$ and
$\tilde b' = j(\tilde\varepsilon - \tilde v)\,\tilde a - M\tilde b$ (each sign
change appears twice and cancels): $(a, -b)$ is an orbital of the problem with
$(M, -v)$ at the level $-\varepsilon$, with the same boundary conditions ($b = 0$
```

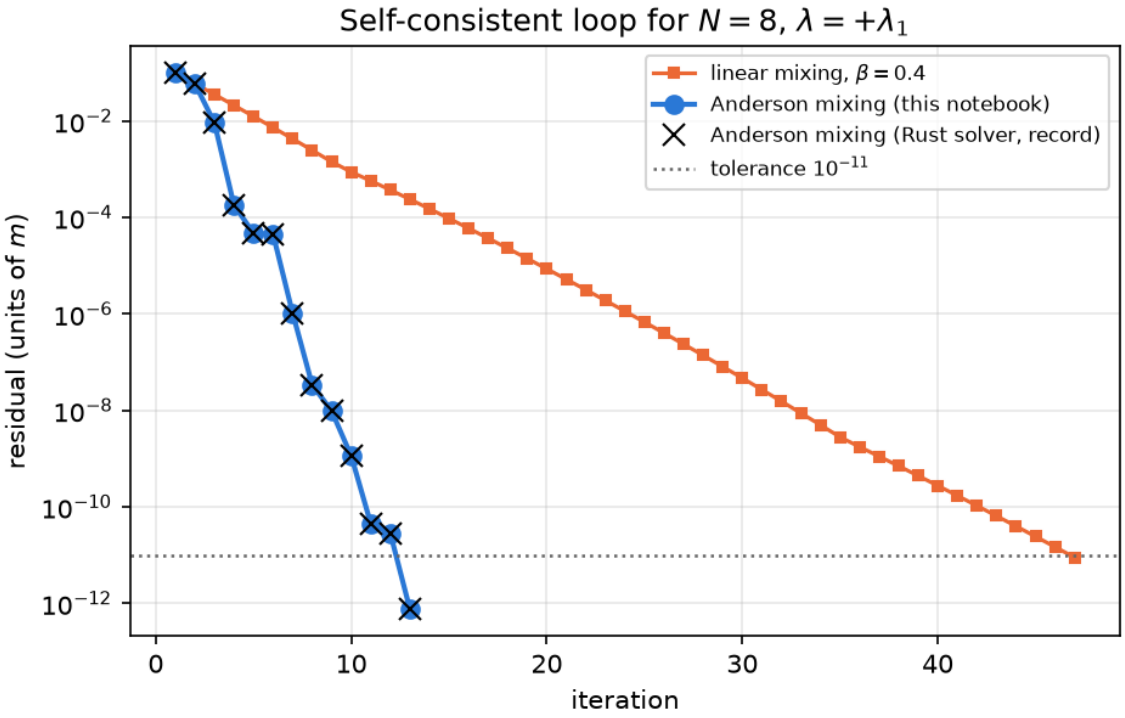

Figure 409: Residual of the self-consistent loop (vertical axis, logarithmic, units of m) against the iteration (horizontal axis) for $N = 8$ with the coupling $+\lambda_1$: linear mixing (orange squares) needs about four times as many iterations as Anderson mixing (blue dots); the crosses are the residuals recorded by the Rust solver, which agree with this notebook's Anderson run. (Notebook 15e, figure 5.)

```
stays $b = 0$) and the same label ($\Phi \to -\Phi$, and the label 0 goes to 0).
(3) Its density $a^2 + b^2$ is the same and its scalar density $2jab$ changes sign,
so $n \to n$ and $S \to -S$. (4) Under $\lambda \to -\lambda$ the potentials of
these densities are $M - m = \tfrac{15}{16}(-\lambda)(-S)$, unchanged, and
$-\tfrac{1}{16}(-\lambda)n = -v$: exactly the potentials assumed in (2), so the
mapped orbitals form a self-consistent state of $-\lambda$ (the loop started from
the free state finds exactly this one, as the check shows). (5) Its energy:
$\sum g f\varepsilon$ changes sign with every level, and
$e_{int} = \lambda(\tfrac{15}{32}S^2 - \tfrac{1}{32}n^2)$ changes sign with
$\lambda$ while $S^2$ and $n^2$ stay; so $E_{KS}(-\lambda) = -E_{KS}(\lambda)$.
```

## 15. The self-consistent potentials of N = 8

The last figure shows the converged potentials of the four couplings. The potential
$v = -\lambda n/16$ follows the proper density of the zero modes, which grows toward
the tip roughly like $e^{2y}e^{-6y} = e^{-4y}$ (the free orbital is $e^{y}$, the
proper volume $e^{6y}$). The mass shift is smaller: the scalar density $S$ of the
zero modes vanishes without interaction (there $b = 0$) and is created only by the
interaction itself; it also vanishes at the tip, where $b(-L) = 0$.
The check confirms the symmetry of the previous section in the potentials:
$M - m$ is the same and $v$ changes sign under $\lambda \to -\lambda$.
```

## 17. What this notebook showed

- The Pruefer angle turns the search for levels into counting: the phase function
  $\Phi(\varepsilon)$ increases strictly, every level is the crossing with one target
  $l\pi$ or $\pi/2 + l\pi$, and no level can be missed (PROVED by the comparison
  argument of section 4; COMPUTED here for the free spectrum).
- RK4 shooting on the solver's grid reproduces the exact free levels (within
  $5 \times 10^{-9}$ for $|\varepsilon| < 4$), the solver's own numbers (within
```

```
  $10^{-12}$) and the fourth order of the method (error ratio 16).
- The brane band has the slope $c\,e^{-a_{4,0}}$ with $c = 1.90514825365$, and the
  slice enters only through $k e^{-a_{4,0}}$ (the rescaling identity): along the
  deflating history every momentum is redshifted.
- A few dozen lines of Python with Anderson mixing reproduce the interacting $N = 8$
  ground states of the Rust solver: energies, levels and the residuals of the loop.
  Linear mixing converges too, but much more slowly.
- For $N = 8$ the energy is exactly odd in $\lambda$, a symmetry of the zero-mode
  state found and checked here.
```

15.9 Line-by-line walk-through of Notebook 15e

The notebook has 15 code cells, In [1] to In [15]. This section explains every line of every one of them, in order: a line or a small group of lines is quoted, then explained. Docstrings (the texts in triple quotes under a `def` line, which say what a function does) and some comment lines are left out of the quotations, and long caption strings in calls of `save_figure` are shortened: the quotation shows the first line of the call and the first line of the caption, and then a line `...)` that stands for the rest of the caption and the closing parenthesis; the complete cells are printed in Section 15.8. Every code cell is preceded in the notebook by a text cell that says what it does.

In [1], the set-up cell. Every line that starts with `#` is a **comment**, which Python skips. The first part of the cell, down to the lines of `-` and `=` signs, is the complete run instructions of Section 15.7 again, as comments, so that the notebook file carries its own instructions. The code starts after the heading THE SET-UP; it computes no physics and is the same in every notebook of the book, except for the line that names the notebook (the notebooks that run a Rust program add two imports and one function, explained in Section 15.14). The other walk-throughs of this chapter refer back to this paragraph.

```
import json  # reads and writes JSON files (text files that hold names and numbers)
import os  # reads the environment variable TEXTBOOK_OUTPUT_ROOT (explained below)
import textwrap  # breaks long printed text into lines of at most 89 characters
from pathlib import Path  # file and folder paths that work on Windows, macOS and Linux
```

`import` loads a **module** (a part of Python or of a package) so that the code can use it. `json`, `os`, `textwrap` and `pathlib` come with Python. `from pathlib import Path` takes the single name `Path` out of the module `pathlib`; a `Path` is the address of a file or a folder, written the same way on every operating system.

```
import matplotlib  # the plotting package
import matplotlib.pyplot as plt  # its drawing functions, called plt by convention
from IPython.display import Image, display  # shows a saved picture below a cell
```

These lines load the plotting package matplotlib, its drawing functions under the short name `plt`, and the two functions `Image` and `display` of IPython (the part of Jupyter that runs Python code), which show a picture file below a cell.

```
NOTEBOOK_ID = "15e"  # this notebook: chapter 15, example e
```

A **variable** is a name for a value; this line gives the name `NOTEBOOK_ID` to the **string** (a text in quotes) `"15e"`. The figure files are named after it.

```
def find_repository_root():
    here = Path.cwd().resolve()  # the folder in which this notebook runs
    for folder in [here, *here.parents]:  # this folder, its parent, its grandparent ...
        if (folder / "Revision" / "textbook" / "requirements.txt").is_file():
            return folder
    raise FileNotFoundError(
        "The repository folder was not found: open this notebook inside the folder "
        "Revision/textbook/notebooks of the repository Dirac_claude")
```

`def` defines a **function**: a named piece of code that runs when it is called. `Path.cwd()` is the folder in which Jupyter runs the notebook (the folder that holds it), and `.resolve()` writes it as a complete address. `here.parents` lists the folders above it; `[here, *here.parents]` is the list that starts with `here` and continues with them (the star unpacks one list into another). The `for` loop visits these folders one after the other. The operator `/` joins a folder and a name into a longer path, and `.is_file()` is true when that file exists. The first folder that contains the file `Revision/textbook/requirements.txt` (the list of the book's packages) is the repository, and `return` hands it back. If no folder qualifies, `raise` stops the notebook with a `FileNotFoundError` whose message says what to do.

```
REPO = find_repository_root()
OUTPUT_ROOT = Path(os.environ.get("TEXTBOOK_OUTPUT_ROOT", str(REPO)))
```

The first line calls the function and names its result `REPO`. It is never printed, because it differs from computer to computer, while the printed output of a notebook must not. The second line chooses where files are written. `os.environ` holds the **environment variables** of the program (named texts that it receives from the computer); `.get(name, default)` returns the value of `TEXTBOOK_OUTPUT_ROOT` if it is set and the default `str(REPO)` (the repository folder as a string) otherwise. When you run the notebook the variable is not set, so the files go into the repository; the book's checking tool sets it to a scratch folder, so that a check never changes a file that git tracks. (Notebook 15e writes nothing else. The notebooks 15a, 15b and 15d, which run the Rust solver, also write the solver's raw output into the folders `Revision/kohn_sham/solver/target/textbook_15a`, `textbook_15b` and `textbook_15d` next to it, about 5.9 MB, 0.9 MB and 0.6 MB; git ignores these folders, and they are written during a check too.)

```
def repository_file(relative):
    return REPO / relative

def output_file(relative):
    path = OUTPUT_ROOT / relative
    path.parent.mkdir(parents=True, exist_ok=True)
    return path
```

Two small functions. `repository_file("Revision/...")` gives the full path of a repository file, for reading a Revision record. `output_file("Revision/...")` gives the full path at which to write

a file; `path.parent.mkdir(parents=True, exist_ok=True)` first creates the folder that will hold it, together with any missing folder above it, and does nothing if the folder exists.

```
def say(text):
    print(textwrap.fill(str(text), width=89, subsequent_indent="    "))
```

`say` prints a text in lines of at most 89 characters, the width of a page of the book; `textwrap.fill` breaks the text at blanks and starts every line after the first with four blanks. This is why some printed lines below continue on an indented second line.

```
matplotlib.rcdefaults()  # ignore personal matplotlib settings: same figures everywhere
plt.rcParams.update({"figure.figsize": (7.0, 4.2), "font.size": 10.0,
                     "axes.grid": True, "grid.alpha": 0.3})
```

matplotlib reads personal settings from a file on your computer if you have one; `matplotlib.rcdefaults()` returns to the built-in settings, so that the figures are the same on every computer. `plt.rcParams.update({...})` then sets four settings for every figure: the size (7.0 by 4.2 inches), the size of the letters (10 points) and a faint grid of lines behind the curves (`grid.alpha` 0.3 means 30 per cent opaque). The braces make a **dictionary**: pairs of a key and a value, written `key: value`.

```
FIGURE_FOLDER = "Revision/textbook/figures"  # where the figures are saved
CAPTION_FILE = f"{FIGURE_FOLDER}/{NOTEBOOK_ID}.captions.json"  # their captions
FIGURE_NUMBERS = {}  # figure name -> its number k (file name <id>_<k>_<name>.png)
CAPTIONS = {}  # figure file name -> caption, written to CAPTION_FILE after every figure
output_file(CAPTION_FILE).write_text("{}\n", encoding="utf-8", newline="\n")
```

A string that starts with `f` is an **f-string**: every name in braces is replaced by its value, so `CAPTION_FILE` is `"Revision/textbook/figures/15e.captions.json"`. `FIGURE_NUMBERS` and `CAPTIONS` start as empty dictionaries. The last line writes the captions file with the empty dictionary `{}` and a line end; `encoding="utf-8"` and `newline="\n"` make the file the same bytes on every operating system.

```
def save_figure(fig, name, caption):
    number = FIGURE_NUMBERS.setdefault(name, len(FIGURE_NUMBERS) + 1)
    file_name = f"{NOTEBOOK_ID}_{number}_{name}.png"
    relative = f"{FIGURE_FOLDER}/{file_name}"
    fig.savefig(output_file(relative), dpi=150, bbox_inches="tight",
                metadata={"Software": None})
    plt.close(fig)  # forget the figure, so that Jupyter does not draw it a second time
    CAPTIONS[file_name] = caption
    output_file(CAPTION_FILE).write_text(
        json.dumps(CAPTIONS, indent=1, sort_keys=True) + "\n", encoding="utf-8",
        newline="\n")
    display(Image(filename=str(output_file(relative))),
            metadata={"textbook_figure": file_name})  # the saved picture itself
    say(f"Figure {NOTEBOOK_ID}.{number} saved as {relative}")
```

`save_figure` is called once for every figure. `setdefault(name, default)` returns the number already given to this figure name, or gives it the next number (one more than the number of figures so far) and returns that; so the figures are numbered 1, 2, 3, ... in the order in which they are first saved. The file name is, for example, `15e_1_phase_function.png`. `fig.savefig` writes the picture: `dpi=150` is the resolution (150 dots per inch), `bbox_inches="tight"` cuts away the empty margin, and `metadata={"Software": None}` stores no program name in the file, so that every run writes exactly the same bytes. `plt.close(fig)` forgets the figure (otherwise Jupyter would draw it a second time). The caption is stored in `CAPTIONS`, and the whole dictionary is written again to the captions file (`json.dumps` turns it into text, `indent=1` puts one entry per line, `sort_keys=True` sorts them). `display(Image(...))` shows the saved picture below the cell, and the last line prints, for example, Figure 15e.1 saved as Revision/textbook/figures/15e_1_phase_function.png.

```
PASSED = []  # the names of the checks that passed, in order

def check(condition, name, record=None):
    if not condition:
        raise AssertionError(f"check failed: {name}")
    PASSED.append(name)
    say(f"PASS {name}")
    if record is not None:
        say(f"     reproduces {record}")
```

`PASSED` is an empty **list** (an ordered collection, in square brackets). `check` is the function behind every check: if the statement `condition` is false (`False`), `raise AssertionError(...)` stops the notebook with an error that names the check; if it is true, the name is appended to `PASSED` and the line PASS name is printed, followed by a line naming the Revision record and its check when the argument `record` is given. (Python's own `assert` statement is not used, because Python started with the option that optimises the code skips it.)

```
def report(label, value, unit=""):
    say(f"RESULT {label} = {value}" + (f" {unit}" if unit else ""))

def all_checks_passed():
    print(f"ALL {len(PASSED)} CHECKS PASSED (notebook {NOTEBOOK_ID})")

say(f"Set-up of notebook {NOTEBOOK_ID} complete: repository folder found, helpers "
    "defined.")
```

`report` prints a key number as a line that starts with RESULT; `(f" {unit}" if unit else "")` adds the unit when one is given. `all_checks_passed` prints the last line of the notebook; `len(PASSED)` is the number of checks that passed. The last statement prints the one output line of In [1], Set-up of notebook 15e complete.

In [2], the grid.

```
import csv  # reads the tables (CSV files) of the Revision record
import math  # exp, sqrt, atan2, pi for single numbers
```

```
import numpy as np  # arrays of numbers
```

`csv` reads tables stored as comma-separated text, `math` holds the mathematical functions for single numbers, and numpy (under the short name `np`) works with **arrays**, lists of numbers on which arithmetic acts entry by entry.

```
H, MASS, L = 1.0, 1.0, 3.0  # the units H = m = 1 and the tip cutoff L = 3
DK = 0.25  # the spacing of the 3-momenta
VOL7 = (2.0 * math.pi / DK) ** 3  # proper 7-volume per unit e^{6Hy} (v_t = 1)
PALETTE = ["#2a78d6", "#eb6834", "#1baf7a", "#eda100", "#e87ba4", "#008300",
           "#4a3aa7", "#e34948"]  # the colours of the figures, in a fixed order
```

The first line gives three names at once: $H = 1$, $m = 1$ (called `MASS`, because the letter m is used for other things below) and $L = 3$. `DK` is $\Delta k = 0.25$. `VOL7` is $\mathrm{Vol}_7 = (2\pi/\Delta k)^3 = 15875.2137$ (Section 15.2); `**` is the power. `PALETTE` is a list of eight colours, written as hexadecimal colour codes.

```
def make_grid(steps):
    points = 2 * steps + 1  # step ends and step midpoints
    y = [-L * ((points - 1 - f) / (points - 1)) for f in range(points)]
    half = 0.5 * L / steps  # the distance between two fine points
    weights = [(4.0 if f % 2 == 1 else 2.0) * half / 3.0 for f in range(points)]
    weights[0] = weights[-1] = half / 3.0  # Simpson: 1, 4, 2, 4, ..., 4, 1 (x h/6)
    return {"steps": steps, "h": L / steps, "points": points, "y": y,
            "ew": [math.exp(-H * v) for v in y], "e6": [math.exp(6 * H * v) for v in y],
            "simpson": np.array(weights)}
```

`make_grid` builds the solver's grid for a given number of RK4 steps. The fine grid has `points` $= 2G+1$ points (the step ends and the step midpoints). The second line is a **list comprehension** (a list built by a `for` inside square brackets): for $f = 0, 1, \ldots, 2G$ it computes $y_f = -L\,(2G - f)/(2G)$, which is $-L$ for $f = 0$ and 0 for $f = 2G$; this is the formula $y_f = -L + f\,h/2$ of Section 15.3 written so that the last point is exactly 0. `half` is the spacing $h/2$. The weights of Simpson's rule with spacing $h/2$ are $\frac{h/2}{3}$ times 4 at the odd points (`f % 2 == 1`: the remainder of f divided by 2 is 1), 2 at the inner even points and 1 at the two ends; the next line sets the two ends (`weights[-1]` is the last entry). The function returns a dictionary with the number of steps, the step $h = L/G$, the number of points, the coordinates, the factors e^{-Hy} (for κ; key `"ew"`) and e^{6Hy} (the proper volume factor; key `"e6"`) at every fine point, and the Simpson weights as an array.

```
GRID = make_grid(900)  # the canonical grid of the solver
Y = np.array(GRID["y"])
E6 = np.array(GRID["e6"])
simpson_test = float(np.sum(GRID["simpson"] * np.exp(Y)))
say(f"fine grid: {GRID['points']} points, step h = {GRID['h']:.6f}")
report("Simpson integral of e^y from -3 to 0", f"{simpson_test:.15f}")
check(abs(simpson_test - (1.0 - math.exp(-3.0))) < 1e-13,
      "Simpson's rule on the fine grid integrates e^y exactly to 1e-13")
```

`GRID` is the canonical grid ($G = 900$); `Y` and `E6` are its coordinates and volume factors as arrays. `simpson_test` is Simpson's rule applied to e^y: the sum of weight times value over the 1801 points

(`np.sum` adds the entries of an array; `float` turns the result into an ordinary number). The exact integral is $\int_{-3}^{0} e^{y}\,dy = 1-e^{-3} = 0.950212931632136$. The format `:.6f` prints six digits after the point, `:.15f` fifteen. Out [2] prints 1801 points, the step 0.003333 and the integral 0.950212931632177, which differs from the exact value by 4×10^{-14}, so the check passes.

In [3], one shooting integration.

```
def rhs(m_y, kk, je, a, b):
    return m_y * a - (kk + je) * b, (je - kk) * a - m_y * b
```

`rhs` (right-hand side) returns the pair (a', b') of the block equation for given values of M (`m_y`), κk (`kk`), $j(\varepsilon - v)$ (`je`), a and b: $a' = Ma - (\kappa k + j(\varepsilon - v))b$ and $b' = (j(\varepsilon - v) - \kappa k)a - Mb$, exactly Section 15.2.

```
def shoot(eps, k, j, a4, mass, pot, grid=GRID, store=False):
    h = grid["h"]
    kk = k * math.exp(-a4)  # k e^{-a4,0}; kappa k = kk e^{-Hy}
    coef = [(mass[f], kk * grid["ew"][f], j * (eps - pot[f]))
            for f in range(grid["points"])]
```

`shoot` integrates from the tip to the brane for the trial energy `eps`, the momentum `k`, the block type `j`, the slice `a4` and the potentials `mass` (M) and `pot` (v), given as lists on the fine grid. The arguments `grid=GRID` and `store=False` have **default values**, used when the caller does not give them. `kk` is $k\,e^{-a_{4,0}}$, so that κk at a point is `kk` times e^{-Hy}. `coef` is a list with one triple $(M, \kappa k, j(\varepsilon - v))$ per fine point, computed once before the integration.

```
    a, b = 1.0, 0.0  # the tip condition b(-L) = 0
    theta, raw = 0.0, 0.0  # the followed angle and the last angle from atan2
    area, r2_prev = 0.0, 1.0  # integral of r^2 (trapezoid) and r^2 at the last node
    nodes = [(a, b)] if store else None
```

The start values: $(a, b) = (1, 0)$ at the tip (the tip condition), the followed angle $\theta = 0$ and the last raw angle 0, the integral of r^2 so far 0, and $r^2 = 1$ at the tip. If `store` is true, the list `nodes` keeps the values at the step ends, starting with the tip; otherwise it is `None` (Python's word for "nothing").

```
    for i in range(grid["steps"]):
        c0, c1, c2 = coef[2 * i], coef[2 * i + 1], coef[2 * i + 2]  # end, mid, end
        k1a, k1b = rhs(*c0, a, b)
        k2a, k2b = rhs(*c1, a + 0.5 * h * k1a, b + 0.5 * h * k1b)
        k3a, k3b = rhs(*c1, a + 0.5 * h * k2a, b + 0.5 * h * k2b)
        k4a, k4b = rhs(*c2, a + h * k3a, b + h * k3b)
        a += h / 6.0 * (k1a + 2.0 * k2a + 2.0 * k3a + k4a)
        b += h / 6.0 * (k1b + 2.0 * k2b + 2.0 * k3b + k4b)
```

The loop makes the G RK4 steps. Step i runs from the fine point $2i$ to the fine point $2i + 2$; its midpoint is the fine point $2i + 1$, so `c0`, `c1`, `c2` are the coefficients at the start, the middle and the end of the step. `rhs(*c0, a, b)` passes the three numbers of the triple `c0` as the first three arguments (the star unpacks it). The four lines compute the four slopes of the classical Runge-Kutta

rule of Chapter 2: k_1 at the start, k_2 and k_3 at the midpoint (from the half-step predictions with k_1 and with k_2), k_4 at the end (from the full-step prediction with k_3). The last two lines advance a and b by $\frac{h}{6}(k_1 + 2k_2 + 2k_3 + k_4)$; `a += x` means `a = a + x`.

```
        new = math.atan2(b, a)
        change = new - raw
        if change > math.pi:  # bring the change of angle into (-pi, pi]
            change -= 2.0 * math.pi
        elif change <= -math.pi:
            change += 2.0 * math.pi
        theta += change
        raw = new
```

These lines follow the Pruefer angle. `math.atan2(b, a)` is the angle of the point (a, b), a number between $-\pi$ and π; it jumps by 2π when the point crosses the negative a-axis. One step is so short that the true angle changes by much less than π; so the change `new - raw` is brought into the interval from $-\pi$ to π by adding or subtracting 2π, and that change is added to `theta`. In this way `theta` follows the angle continuously and may grow beyond 2π (Section 15.3).

```
        r2 = a * a + b * b
        area += 0.5 * h * (r2_prev + r2)  # trapezoid rule over this step
        r2_prev = r2
        if store:
            nodes.append((a, b))
    return j * theta, area / r2_prev, nodes
```

`r2` is $r^2 = a^2 + b^2$ at the new step end; the trapezoid rule adds $\frac{h}{2}(r_i^2 + r_{i+1}^2)$ for the step. When `store` is true, the new values are appended to `nodes`. After the loop the function returns three things: $\Phi = j\,\theta(0)$, the derivative $d\Phi/d\varepsilon = \int r^2 dy / r(0)^2$ (`r2_prev` now holds $r(0)^2$), and the stored values.

```
FREE_MASS = [MASS] * GRID["points"]  # M = m everywhere (no interaction)
FREE_POT = [0.0] * GRID["points"]  # v = 0 everywhere
phi_zero, _, _ = shoot(0.0, 0.0, 1, 0.0, FREE_MASS, FREE_POT)
report("Phi(0) for k = 0, j = +1 (the zero mode: b stays 0)", phi_zero)
check(phi_zero == 0.0, "at eps = 0 and k = 0 the Pruefer angle stays exactly 0")
```

`[MASS] * n` is a list of n copies of 1.0: the free potentials $M = m$ and $v = 0$ on the 1801 fine points. The shot at $\varepsilon = 0$, $k = 0$, $j = +1$, $a_{4,0} = 0$ is the zero mode; the underscores `_` receive the two results that are not needed. With $k = 0$ and $\varepsilon - v = 0$ the equation for b is $b' = -Mb$, and $b = 0$ at the tip; so every RK4 stage gives exactly $b = 0$, `atan2(0, a)` is exactly 0 for $a > 0$, and $\Phi = 0$ without any rounding error. Out [3] prints the RESULT line with the value 0.0 and the PASS line. The text cell that follows the cell in the notebook repeats the derivation of $d\Phi/d\varepsilon$ of Section 15.3.

In [4], the phase function.

```
energies = np.linspace(-4.0, 4.0, 401)  # 401 trial energies
phase = np.array([shoot(e, 0.0, 1, 0.0, FREE_MASS, FREE_POT)[0] for e in energies])
```

`np.linspace(-4.0, 4.0, 401)` makes 401 equally spaced numbers from -4 to 4 (spacing 0.02). For each of them the cell shoots with $k = 0$, $j = +1$ and no interaction and keeps the first result, Φ (`[0]` takes the first entry of the returned triple).

```
fig, ax = plt.subplots(figsize=(7.5, 4.5))
ax.plot(energies, phase / math.pi, color=PALETTE[0], lw=2.0,
        label="$\\Phi(\\varepsilon)/\\pi$, $k = 0$, $j = +1$")
for whole in range(-4, 5):
    ax.axhline(whole, color=PALETTE[1], lw=0.8, alpha=0.7)  # even targets l pi
    ax.axhline(whole + 0.5, color=PALETTE[2], lw=0.8, ls="--", alpha=0.7)  # odd
ax.plot([], [], color=PALETTE[1], lw=0.8, label="even targets $l$")
ax.plot([], [], color=PALETTE[2], lw=0.8, ls="--", label="odd targets $l + 1/2$")
```

`plt.subplots` makes a figure `fig` with one drawing area `ax` of 7.5 by 4.5 inches. `ax.plot` draws Φ/π against ε as a blue line of width 2 (`lw`); the `label` is the text of the legend, written in the math notation of matplotlib (a doubled backslash in a Python string is one backslash). The loop draws horizontal lines (`axhline`) at the whole numbers -4 to 4 (the even targets $l\pi$, divided by π) and dashed lines (the line style `ls` set to two hyphens) half-way between them (the odd targets); `alpha=0.7` makes them slightly transparent. The two `ax.plot([], [], ...)` lines draw nothing (empty lists) but put the two kinds of lines into the legend.

```
ax.set_xlabel("trial energy $\\varepsilon$ (units of $m$)")
ax.set_ylabel("$\\Phi(\\varepsilon) / \\pi$")
ax.set_title("The phase function counts the levels")
ax.set_ylim(-3.2, 3.2)
ax.legend(fontsize=8, loc="upper left")
save_figure(fig, "phase_function",
            "The phase function $\\Phi(\\varepsilon)/\\pi$ (vertical axis) of the "
...)
check(bool(np.all(np.diff(phase) > 0.0)), "Phi increases strictly at all 400 steps")
```

These lines label the axes, set the title, show the vertical range from -3.2 to 3.2 and draw the legend in the upper left corner. `save_figure` saves Figure 15e.1 with its caption (shortened here; the complete caption is printed under the figure in Section 15.8). `np.diff(phase)` is the array of the 400 differences between neighbouring values; `> 0.0` compares each with 0, and `np.all` is true when every comparison is true. Out [4] prints the figure line and PASS: Φ increases at all 400 steps, as Section 15.3 proved. In the figure the curve is nearly flat between the levels ± 1.29 around $\varepsilon = 0$ (there it passes the zero mode at $\Phi = 0$) and climbs steeply through each level; this is the gap of the free field.

In [5], Newton's method inside a bracket.

```
def target(parity, label):
    return label * math.pi + (0.0 if parity == "even" else 0.5 * math.pi)
```

The target t_l of a level: $l\pi$ for even parity, $\pi/2 + l\pi$ for odd parity. `a if condition else b` is Python's choice between two values.

```
def find_level(k, j, parity, label, a4, mass, pot, guess, grid=GRID, tol=1e-13):
    t = target(parity, label)
    def g(e):  # Phi - target and its derivative at the energy e
        phi, dphi, _ = shoot(e, k, j, a4, mass, pot, grid)
        return phi - t, dphi
    ec = guess
    gc, dc = g(ec)
    if gc == 0.0:
        return ec
    step = min(max(abs(gc / dc) * 1.2, 1e-4), 2.0)  # the first trial step
```

`find_level` returns the energy of the level with the given momentum, block type, parity and label in the given potentials, starting from the energy `guess`. The inner function `g` shoots at the energy `e` and returns $\Phi - t_l$ and $d\Phi/d\varepsilon$. `ec`, `gc`, `dc` are the current energy, its value of $\Phi - t_l$ and its derivative. If the guess hits the target exactly, it is returned at once. The first trial step is 1.2 times the Newton estimate $|\Phi - t_l|/\Phi'$ of the distance to the root, but at least 10^{-4} and at most 2.

```
    if gc < 0.0:  # Phi is too small: walk up until Phi - t >= 0
        lo = ec
        while True:
            e = lo + step
            ge, de = g(e)
            if ge >= 0.0:
                hi = e  # now [lo, hi] brackets the root
                if abs(ge) < abs(gc):
                    ec, gc, dc = e, ge, de  # keep the better end for Newton
                break
            lo, ec, gc, dc = e, e, ge, de
            step *= 2.0  # double the step
```

If Φ is below the target, the root lies higher (because Φ increases). The loop `while True` repeats until `break`: it tries the energy `lo + step`; if $\Phi - t_l$ is no longer negative there, the root lies between `lo` and this energy, which becomes `hi`, and the end with the smaller $|\Phi - t_l|$ becomes the start of Newton's method; otherwise the trial energy becomes the new `lo` and the step is doubled. Doubling reaches any distance in a few steps.

```
    else:  # Phi is too large: walk down until Phi - t <= 0
        hi = ec
        while True:
            e = hi - step
            ge, de = g(e)
            if ge <= 0.0:
                lo = e
                if abs(ge) < abs(gc):
                    ec, gc, dc = e, ge, de
                break
            hi, ec, gc, dc = e, e, ge, de
            step *= 2.0
    if gc == 0.0:
        return ec
```

The mirror image: if Φ is above the target, the walk goes down until $\Phi - t_l \le 0$. Afterwards `[lo, hi]` brackets the root; if one end hit it exactly, it is returned.

```
    previous = math.inf
    for _ in range(300):
        if hi - lo <= tol:
            break
        new = ec - gc / dc  # the Newton step
        bisect = not lo < new < hi or abs(gc) > 0.5 * previous
        if bisect:
            new = 0.5 * (lo + hi)  # bisection instead
        previous = abs(gc)
        moved = abs(new - ec)  # how far this step moved the energy
        ec = new
        gc, dc = g(ec)
        if gc == 0.0:
            break
        if gc < 0.0:
            lo = ec
        else:
            hi = ec
        if moved <= tol and not bisect:
            break  # a Newton step that moves less than tol: converged
    return ec
```

The refinement, at most 300 steps (`for _ in range(300)` repeats 300 times without using the counter). It stops when the bracket is shorter than the tolerance 10^{-13}. Otherwise it computes the Newton step $\varepsilon - (\Phi - t_l)/\Phi'$. `bisect` is true when the Newton point is not strictly inside the bracket, or when the previous step did not halve $|\Phi - t_l|$ (`previous` holds the earlier value; it starts as infinity, `math.inf`, so the first step is never rejected for this reason); then the midpoint of the bracket is used instead. After the step the new energy is evaluated, the bracket end on the same side of the root is replaced (the sign of $\Phi - t_l$ tells the side), and the loop stops when a Newton step moved the energy by at most the tolerance. This is the solver's rule of Section 15.3. The cell defines functions only and prints nothing.

In [6], the exact levels at $k = 0$ and the solver's levels.

```
def odd_momentum(n):
    lo, hi = (n - 0.5) * math.pi / L, n * math.pi / L
    f = lambda p: MASS * math.sin(p * L) + p * math.cos(p * L)
    for _ in range(200):
        mid = 0.5 * (lo + hi)
        lo, hi = (mid, hi) if f(lo) * f(mid) > 0.0 else (lo, mid)
    return 0.5 * (lo + hi)
```

The odd levels need the roots p of $\tan(pL) = -p/M$ (Section 15.3). Multiplied by $M\cos(pL)$ this is $f(p) = M\sin(pL) + p\cos(pL) = 0$, which has no division. The n-th root lies between $(n - \frac{1}{2})\pi/L$ and $n\pi/L$: at the left end $\cos(pL) = 0$ and $f = \pm M$, at the right end $\sin(pL) = 0$ and $f = \pm p$ with the opposite sign, so f changes sign in between. `lambda p: ...` defines a small function without a name. The loop is **bisection**: if f has the same sign at `lo` and at the midpoint (their product is

positive), the root lies in the right half, otherwise in the left half. After 200 halvings the interval is far below rounding size, and its midpoint is returned.

```
def exact_level(parity, label):
    if parity == "even":
        n = abs(label)
        return math.copysign(math.sqrt(MASS ** 2 + (n * math.pi / L) ** 2), label) \
            if n else 0.0
    n = label + 1 if label >= 0 else -label  # labels 0, 1, ... and -1, -2, ...
    return math.copysign(math.sqrt(MASS ** 2 + odd_momentum(n) ** 2), label + 0.5)
```

The exact free level at $k = 0$ with a given parity and label. For even parity the label l belongs to $n = |l|$ and the level is $\pm\sqrt{M^2 + (n\pi/L)^2}$ with the sign of l (`math.copysign(x, s)` is $|x|$ with the sign of s); the label 0 is the zero mode, $\varepsilon = 0$ (`if n else 0.0`: a nonzero n counts as true). The backslash at the end of a line continues the statement on the next line. For odd parity the labels $0, 1, 2, \ldots$ are the positive levels with $n = l + 1$, and the labels $-1, -2, \ldots$ the negative ones with $n = -l$; the sign is that of $l + \frac{1}{2}$, which is positive for $l \geq 0$ and negative for $l \leq -1$.

```
RECORD_FREE = "Revision/kohn_sham/results/spectrum/free-k0-analytic.csv"
recorded = {}
for line in repository_file(RECORD_FREE).read_text(encoding="utf-8").split("\n")[1:]:
    if line:
        m_, l_, parity, label, eps_num, eps_exact, _ = line.split(",")
        if float(m_) == 1.0 and float(l_) == 3.0:
            recorded[(parity, int(label))] = (float(eps_num), float(eps_exact))
```

The record file of the solver's free spectra at $k = 0$ is read as text, split into lines, and the first line (the column names) is skipped (`[1:]` takes everything from the second entry on). Each nonempty line is split at the commas into seven fields: the mass, L, the parity, the label, the solver's numerical level, the exact level and one more column that is not needed. Only the rows with $M = 1$ and $L = 3$ are kept (the record also tests other masses and lengths), in a dictionary whose key is the pair (parity, label).

```
worst_exact, worst_record = 0.0, 0.0
say("parity label   shooting          exact              difference")
for parity in ("even", "odd"):
    for label in range(-3, 6):
        exact = exact_level(parity, label)
        found = find_level(0.0, 1, parity, label, 0.0, FREE_MASS, FREE_POT, exact + 0.01)
        say(f"{parity:5} {label:3d}  {found:17.13f}  {exact:17.13f}"
            f"  {found - exact:10.2e}")
        if abs(exact) < 4.0:
            worst_exact = max(worst_exact, abs(found - exact))
        if (parity, label) in recorded:
            worst_record = max(worst_record, abs(found - recorded[(parity, label)][0]))
```

For both parities and the labels -3 to 5 the cell computes the exact level, finds the level by shooting (with the guess 0.01 above the exact value), and prints a table row: the parity in 5 characters, the label in 3 digits, both levels with 13 digits after the point, and their difference in the exponent

format `.2e` (two digits after the point and a power of ten). The largest difference is kept for $|\varepsilon| < 4$ (`worst_exact`; the record uses the same range for its tolerance), and the largest difference to the solver's recorded value for every row present in the record (`worst_record`).

```
report("largest |shooting - exact| for |eps| < 4", f"{worst_exact:.2e}")
report("largest |this notebook - solver record|", f"{worst_record:.2e}")
check(worst_exact < 5e-9,
      "the shooting levels equal the exact levels within 5e-9 for |eps| < 4",
      record="Revision/kohn_sham/reports/ks-rust-solver.json, check "
             "free_k0_analytic_spectra")
check(worst_record < 1e-12, "the levels equal the solver's levels within 1e-12",
      record=f"{RECORD_FREE}, column eps_numeric")
```

Out [6] shows the table. The differences grow with the energy, from 10^{-13} near ± 1.3 to 6.7×10^{-9} at the odd label 5 ($\varepsilon = 5.90$): the error of RK4 grows like $(h\varepsilon)^4$, because a higher level oscillates faster. The largest difference for $|\varepsilon| < 4$ is 7.23×10^{-10}, the value of the record's check free_k0_analytic_spectra. The first check therefore tests the tolerance 5×10^{-9} only for $|\varepsilon| < 4$, as the record does, and its PASS line says so (the check name is written on its own line of the call because the call would otherwise be longer than a line of the page); for $4 \le |\varepsilon| < 7$ the record allows 3×10^{-7}, far above the 6.7×10^{-9} of the table. The largest difference to the solver's own numbers is 7.99×10^{-15}: the Python code and the Rust program do the same arithmetic in a slightly different order. Both checks pass. The even label 0 is printed as -0.0000000000000, a difference of -1.4×10^{-19} from the exact zero, left by Newton's method.

In [7], orbitals with Hermite midpoints.

```
def orbital(eps, k, j, a4, mass, pot, grid=GRID):
    _, _, nodes = shoot(eps, k, j, a4, mass, pot, grid, store=True)
    h = grid["h"]
    kk = k * math.exp(-a4)
    a = np.zeros(grid["points"])
    b = np.zeros(grid["points"])
    a[0::2] = [p[0] for p in nodes]  # the step ends
    b[0::2] = [p[1] for p in nodes]
```

`orbital` returns the normalised orbital of a level on the whole fine grid. It shoots once more at the level's energy and keeps the values at the $G + 1$ step ends. `np.zeros(n)` is an array of n zeros. `a[0::2]` is every second entry starting with the first (the fine indices $0, 2, 4, \ldots$, the step ends), and the step-end values are written there.

```
    f = np.arange(0, grid["points"], 2)  # fine indices of the step ends
    m_y = np.array(mass)[f]
    kap = kk * np.array(grid["ew"])[f]
    je = j * (eps - np.array(pot)[f])
    da = m_y * a[f] - (kap + je) * b[f]  # derivatives from the equation
    db = (je - kap) * a[f] - m_y * b[f]
```

`np.arange(0, n, 2)` is the array $0, 2, 4, \ldots$ of the step-end indices; indexing an array with it picks those entries. So `m_y`, `kap` and `je` are M, κk and $j(\varepsilon - v)$ at the step ends, and `da`, `db` are the

derivatives a', b' there, computed from the block equation itself (this is where the Hermite formula gets its derivatives).

```
    a[1::2] = 0.5 * (a[f][:-1] + a[f][1:]) + h / 8.0 * (da[:-1] - da[1:])
    b[1::2] = 0.5 * (b[f][:-1] + b[f][1:]) + h / 8.0 * (db[:-1] - db[1:])
    norm = math.sqrt(float(np.sum(grid["simpson"] * (a * a + b * b))))
    return a / norm, b / norm
```

`a[1::2]` are the midpoints. For each step, `a[f][:-1]` is the value at its start (all step ends but the last) and `a[f][1:]` the value at its end (all but the first); the line is the Hermite formula $\frac{1}{2}(u_0+u_1)+\frac{h}{8}(u_0'-u_1')$ of Section 15.3, for all steps at once. Then Simpson's rule gives $\int (a^2+b^2)\,dy$, and both components are divided by its square root, so the returned orbital is normalised.

```
zero_a, zero_b = orbital(0.0, 0.0, 1, 0.0, FREE_MASS, FREE_POT)
bulk_eps = find_level(0.0, 1, "even", 1, 0.0, FREE_MASS, FREE_POT, 1.4)
bulk_a, bulk_b = orbital(bulk_eps, 0.0, 1, 0.0, FREE_MASS, FREE_POT)
band_eps = find_level(0.5, 1, "even", 0, 0.0, FREE_MASS, FREE_POT, 0.8)
band_a, band_b = orbital(band_eps, 0.5, 1, 0.0, FREE_MASS, FREE_POT)
```

Three orbitals of the free block $j=+1$: the zero mode ($\varepsilon=0$, $k=0$); the first even bulk level at $k=0$ (label 1, guess 1.4; its energy is 1.4479719, Out [6]); and the brane-band level at $k=0.5$ (the shell $n_2=4$; label 0, guess 0.8). Their energies appear in the panel titles of the figure.

```
fig, axes = plt.subplots(1, 3, figsize=(10.5, 3.6), sharey=True,
                         layout="constrained")
for ax, (a, b, title) in zip(axes, [
        (zero_a, zero_b, "zero mode, $k = 0$, $\\varepsilon = 0$"),
        (bulk_a, bulk_b, f"bulk, $k = 0$, $\\varepsilon = {bulk_eps:.4f}$"),
        (band_a, band_b, f"brane band, $k = 0.5$, $\\varepsilon = {band_eps:.4f}$")]):
    ax.plot(Y, a, color=PALETTE[0], lw=2.0, label="$a(y)$")
    ax.plot(Y, b, color=PALETTE[1], lw=2.0, ls="--", label="$b(y)$")
    ax.set_title(title, fontsize=9)
    ax.set_xlabel("hidden coordinate $y$")
axes[0].set_ylabel("orbital (normalised)")
axes[0].legend()
save_figure(fig, "orbitals",
            "Three normalised orbitals of the free block $j = +1$ (components $a$, "
...)
```

`plt.subplots(1, 3, ...)` makes one row of three drawing areas (`axes`), which share the vertical axis (`sharey=True`); `layout="constrained"` spaces them so that no labels overlap. `zip` pairs each drawing area with one triple (the two components and a title), and the loop draws a solid and b dashed against y. The first panel gets the vertical label and the legend, and `save_figure` saves Figure 15e.2. The student should see that the zero mode is e^{y} and sits at the brane with $b=0$ everywhere, that the bulk orbital fills the whole interval, and that the band orbital is again bound to the brane; every b vanishes at both ends.

```
exact_zero = math.sqrt(2.0 * MASS / (1.0 - math.exp(-2.0 * MASS * L))) * np.exp(MASS * Y)
zero_error = max(float(np.max(np.abs(zero_a - exact_zero))),
```

```
                float(np.max(np.abs(zero_b))))
report("largest deviation of the zero mode from its exact form", f"{zero_error:.2e}")
check(zero_error < 1e-11, "the zero mode is (e^{My}, 0), normalised, to 1e-11",
      record="Revision/kohn_sham/reports/ks-rust-solver.json, check "
             "free_zero_mode_exact")
```

`exact_zero` is the normalised zero mode $\sqrt{2M/(1-e^{-2ML})}\,e^{My}$ of Section 15.3 on the fine grid. `zero_error` is the larger of the largest deviation of a from it and the largest $|b|$. Out [7] prints 1.35×10^{-12}, the value of the record's check free_zero_mode_exact, and PASS.

In [8], the order 4 of RK4.

```
STEPS = [100, 200, 400, 800]
errors = {2: [], 3: []}
for steps in STEPS:
    grid = make_grid(steps)
    mass = [MASS] * grid["points"]
    pot = [0.0] * grid["points"]
    for label in errors:
        found = find_level(0.0, 1, "even", label, 0.0, mass, pot,
                           exact_level("even", label), grid=grid)
        errors[label].append(abs(found - exact_level("even", label)))
```

For the grids of 100, 200, 400 and 800 steps the cell finds the even levels with the labels 2 and 3 at $k = 0$ (exact values $\sqrt{1+(2\pi/3)^2} = 2.3208815$ and $\sqrt{1+\pi^2} = 3.2969083$) and appends the size of the error to a list for each label. Looping over a dictionary (`for label in errors`) visits its keys, 2 and 3.

```
ratios = []
for label, errs in errors.items():
    steps_ratios = [errs[i] / errs[i + 1] for i in range(len(errs) - 1)]
    ratios += steps_ratios
    say(f"label {label}: errors " + ", ".join(f"{e:.2e}" for e in errs)
        + "; ratios " + ", ".join(f"{r:.2f}" for r in steps_ratios))
```

For each label the three ratios of the error on one grid to the error on the grid with twice as many steps are computed, collected in `ratios` and printed (`", ".join(...)` writes the numbers separated by commas). Out [8] shows the errors 2.45×10^{-7}, 1.53×10^{-8}, 9.59×10^{-10}, 5.99×10^{-11} for the label 2 and ratios between 15.96 and 16.00.

```
steps_h = [L / s for s in STEPS]
fig, ax = plt.subplots()
for colour, (label, errs) in zip(PALETTE, errors.items()):
    ax.loglog(steps_h, errs, "o-", color=colour, lw=2.0, ms=7,
              label=f"even level $l = {label}$")
ax.loglog(steps_h, [errors[3][0] * (s / steps_h[0]) ** 4 for s in steps_h], "--",
          color="0.4", lw=1.2, label="slope 4: error $\\propto h^4$")
```

`steps_h` are the steps $h = 3/G$. `ax.loglog` draws with logarithmic scales on both axes; the style `"o-"` draws dots joined by lines, `ms` is the size of the dots. On such axes a power law error $= Ch^4$ is

a straight line of slope 4; the dashed grey line (`color="0.4"` is a grey) is that law through the first error of the label 3.

```
ax.set_xlabel("step $h$ (units of $1/m$)")
ax.set_ylabel("|shooting level - exact level| (units of $m$)")
ax.set_title("RK4: halving the step divides the error by 16")
ax.legend()
save_figure(fig, "rk4_convergence",
            "Error of two shooting levels (vertical axis, logarithmic, units of $m$) "
...)
middle = sorted(ratios)[len(ratios) // 2]
report("median error ratio for halving the step", f"{middle:.2f}")
check(15.0 < middle < 17.0, "the error ratio is 16 within 1 (fourth order)",
      record="Revision/kohn_sham/reports/ks-rust-determinism.json, check "
             "refined_free_spectra_convergence_order")
```

After the labels and the legend, `save_figure` saves Figure 15e.3. `sorted(ratios)` sorts the six ratios; the entry at the position `len(ratios) // 2` (`//` divides and drops the remainder; here position 3) is the **median**, the middle value. It is 16.00, the ratio 2^4 of a fourth-order method, the same number as in the record's check refined_free_spectra_convergence_order. In the figure the dots lie on lines parallel to the dashed line of slope 4.

In [9], the brane band and the redshift.

```
THEORY = json.loads(repository_file("Revision/kohn_sham/ks-theory.json").read_text(
    encoding="utf-8"))  # the theory file of the solver
C_RECORD = float(THEORY["checksNumeric"]["braneBandSlope_M1_H1_L3_a0"])
c_formula = (2 * MASS / (2 * MASS - H) * (1 - math.exp(-(2 * MASS - H) * L))
             / (1 - math.exp(-2 * MASS * L)))
```

`json.loads` turns the text of the theory file into Python dictionaries and lists. `C_RECORD` is the recorded slope $c = 1.9051482536448664$, and `c_formula` computes $c = \frac{2M}{2M-H} \cdot \frac{1-e^{-(2M-H)L}}{1-e^{-2ML}}$ of Section 15.4 again.

```
def band(k, a4):
    return find_level(k, 1, "even", 0, a4, FREE_MASS, FREE_POT, 1.9 * k * math.exp(-a4))
```

`band(k, a4)` is the brane-band level: block type +1, even parity, label 0, free potentials, with the guess $1.9\,k\,e^{-a_{4,0}}$ from the small-k law.

```
momenta = np.linspace(0.0, 2.0, 41)
fig, ax = plt.subplots()
slopes = []
for shade, a4 in zip(("#86b6ef", "#2a78d6", "#104281"), (0.0, 1.0, 2.0)):
    curve = [band(k, a4) for k in momenta]
    ax.plot(momenta, curve, "o-", color=shade, ms=4, lw=1.8,
            label=f"$a_{{4,0}} = {a4:.0f}$")
    ax.plot(momenta, c_formula * momenta * math.exp(-a4), ":", color=shade, lw=1.2)
```

For the slices $a_{4,0} = 0, 1, 2$ (in light, middle and dark blue) the cell computes the band at 41 momenta from 0 to 2 and draws it, together with the dotted tangent $c\,k\,e^{-a_{4,0}}$. In an f-string a doubled brace `{{` prints one brace, so the label reads $a_{4,0} = 0$ and so on.

```
    s1, s2 = band(1e-4, a4) / 1e-4, band(2e-4, a4) / 2e-4  # s(k) and s(2k)
    slopes.append((4.0 * s1 - s2) / 3.0 * math.exp(a4))  # slope times e^{a4,0}
    if a4 == 0.0:
        s4 = band(4e-4, a4) / 4e-4  # s(4k), to measure how the error grows
        growth = (s4 - s2) / (s2 - s1)  # 4 if the error of s is proportional to k^2
```

Still inside the loop: $s(k) = \varepsilon(k)/k$ at $k = 10^{-4}$ and 2×10^{-4}. The band is an odd function of k (the text cell before In [9] derives this from the two block symmetries), so $\varepsilon = ck - dk^3 + \ldots$ and $s(k) = c - dk^2 + \ldots$; the **Richardson extrapolation** $\frac{1}{3}(4s(k) - s(2k))$ removes the k^2 term: $4(c - dk^2) - (c - 4dk^2) = 3c$. Multiplied by $e^{a_{4,0}}$ it must be the slice-independent c. At the first slice the cell also computes $s(4k)$ and the ratio of the changes $(s(4k) - s(2k))/(s(2k) - s(k))$, which is $(16 - 4)/(4 - 1) = 4$ if the error of s is proportional to k^2.

```
ax.plot([], [], ":", color="0.4", label="$c\\,k\\,e^{-a_{4,0}}$")
ax.set_xlabel("3-momentum $k$ (units of $m$)")
ax.set_ylabel("brane-band level $\\varepsilon$ (units of $m$)")
ax.set_title("The brane band redshifts along the history")
ax.legend()
save_figure(fig, "brane_band",
            "The brane-band level $\\varepsilon(k)$ (vertical axis, units of $m$) "
...)
rescale = max(abs(band(k, a4) - band(k * math.exp(-a4), 0.0))
              for k in (0.25, 1.0, 2.5) for a4 in (0.5, 1.0, 2.0))
```

After the legend entry for the dotted tangents and the labels, `save_figure` saves Figure 15e.4. `rescale` is the largest violation of the rescaling identity $\varepsilon(k; a_{4,0}) = \varepsilon(k\,e^{-a_{4,0}}; 0)$ for three momenta and three slices; the two `for` clauses inside `max(...)` run over all nine pairs.

```
report("growth of the error of eps(k)/k when k doubles", f"{growth:.4f}")
report("slope c times e^{a4,0} at a4,0 = 0, 1, 2",
       ", ".join(f"{s:.10f}" for s in slopes))
report("largest violation of the rescaling identity", f"{rescale:.1e}")
check(abs(c_formula - C_RECORD) < 1e-14 and
      max(abs(s - C_RECORD) for s in slopes) < 1e-9 * C_RECORD,
      "the brane-band slope is c e^{-a4,0} with c = 1.9051482536",
      record="Revision/kohn_sham/reports/ks-rust-solver.json, check "
             "free_brane_band_slope")
check(rescale < 1e-12, "eps(k, a4,0) = eps(k e^{-a4,0}, 0) within 1e-12",
      record="Revision/kohn_sham/reports/ks-rust-solver.json, check "
             "free_rescaling_relation_and_band_monotone")
```

Out [9] prints the growth factor 4.0000, the three extrapolated slopes, each 1.9051482536, and the violation 0.0, and both checks pass. The violation is exactly zero, not merely small, because the two calls do the same arithmetic: `shoot` uses k only through the product $k\,e^{-a_{4,0}}$, and $k\,e^{-a_{4,0}}$ at the slice $a_{4,0}$ and $(k\,e^{-a_{4,0}})\,e^{0}$ at the slice 0 are the same number. In Figure 15e.4 each band curve is

the previous one with the momentum axis stretched by $e = 2.718$, and every curve lies below its dotted tangent.

In [10], the self-consistent loop.

```
POINTS = GRID["points"]
P_FACTOR = 1.0 / (E6 * VOL7)  # P = e^{-6Hy}/Vol_7 on the fine grid
```

`POINTS` is 1801, and `P_FACTOR` is the array of $P = e^{-6Hy}/\mathrm{Vol}_7$ at the fine points (Section 15.2).

```
def iteration(x, lam, a4, guesses):
    mass = (MASS + x[:POINTS]).tolist()
    pot = x[POINTS:].tolist()
    n = np.zeros(POINTS)
    s = np.zeros(POINTS)
    levels = {}
```

`iteration` performs one Kohn-Sham iteration for $N = 8$. The input `x` is the array of the 2×1801 unknowns: its first half (`x[:POINTS]`) is $M - m$ and its second half (`x[POINTS:]`) is v; they become the lists `mass` and `pot` that `shoot` expects (`.tolist()`). The densities n and S start at zero, and `levels` will hold the two occupied levels.

```
    for j in (1, -1):  # the two block types, each level four-fold (g = 4)
        eps = find_level(0.0, j, "even", 0, a4, mass, pot, guesses.get(j, 0.0))
        a, b = orbital(eps, 0.0, j, a4, mass, pot)
        weight = 0.5 * 4.0 * 1.0  # w g f with w = 1/2 (the Z2 doubling)
        n += weight * P_FACTOR * (a * a + b * b)
        s += weight * P_FACTOR * j * 2.0 * a * b
        levels[j] = eps
```

For each block type the occupied level is the zero mode: $k = 0$, even parity, label 0. Its energy is found starting from the previous iteration's energy (`guesses.get(j, 0.0)` gives 0 in the first iteration, when `guesses` is empty), and its orbital is computed. The weight $wgf = \frac{1}{2} \cdot 4 \cdot 1 = 2$ multiplies the orbital densities $P(a^2 + b^2)$ and $P\, j\, 2ab$, which are added to n and S (the formulas of Section 15.2).

```
    x_out = np.concatenate([lam * (15.0 / 16.0) * s, lam * (-1.0 / 16.0) * n])
    e_int = lam * (15.0 / 32.0 * s * s - 1.0 / 32.0 * n * n)
    energy = sum(4.0 * e for e in levels.values()) \
        - 2.0 * VOL7 * float(np.sum(GRID["simpson"] * E6 * e_int))
    return float(np.max(np.abs(x_out - x))), x_out, energy, levels
```

The output potentials are $\frac{15}{16}\lambda S$ and $-\frac{1}{16}\lambda n$, joined into one array (`np.concatenate`). `e_int` is the interaction energy density, and `energy` is $E_{KS} = \sum gf\varepsilon - 2\,\mathrm{Vol}_7 \int e^{6Hy} e_{int}\, dy$ with $gf = 4$ for each of the two levels and Simpson's rule for the integral. The function returns the size of the residual (the largest $|x_{out} - x|$), the output potentials, the energy and the levels.

```
class Anderson:
    def __init__(self, depth=6, beta=0.4):
        self.depth, self.beta = depth, beta
        self.xs, self.rs, self.best = [], [], math.inf
```

A **class** defines a new kind of object that keeps data between calls. An `Anderson` object stores the depth 6, the factor $\beta = 0.4$, the lists of the last inputs `xs` and residuals `rs`, and the smallest residual size seen so far, `best`. `__init__` runs when the object is made; `self` is the object itself.

```
    def next(self, x, r):
        size = float(np.max(np.abs(r)))
        if size > 10.0 * self.best and self.xs:
            self.xs, self.rs = [], []  # the residual grew tenfold: start again
        self.best = min(self.best, size)
        self.xs = (self.xs + [x.copy()])[-self.depth:]
        self.rs = (self.rs + [r.copy()])[-self.depth:]
        count = len(self.xs)
```

`next` receives the current input and residual and returns the next input. If the residual is more than ten times the smallest one seen and there is a history, the history is forgotten (an empty list counts as false, a nonempty one as true). The new pair is appended, and `[-self.depth:]` keeps only the last six. `count` is the number p of stored pairs.

```
        system = np.zeros((count + 1, count + 1))
        gram = np.array([[float(np.dot(u, v)) for v in self.rs] for u in self.rs])
        system[:count, :count] = gram + 1e-12 * np.max(np.diag(gram)) * np.eye(count)
        system[:count, count] = 1.0
        system[count, :count] = 1.0
        right = np.zeros(count + 1)
        right[count] = 1.0
        weights = np.linalg.solve(system, right)[:count]
        return sum(c * (xi + self.beta * ri)
                   for c, xi, ri in zip(weights, self.xs, self.rs))
```

These lines build and solve the bordered system of Section 15.5. `gram` is the Gram matrix $G_{ik} = r_i \cdot r_k$ (`np.dot` is the dot product of two arrays). The upper left block of `system` is G plus 10^{-12} times its largest diagonal entry on the diagonal (`np.eye(count)` is the unit matrix), the last column and the last row (without the corner) are ones, and the right side is $(0, \ldots, 0, 1)$. `np.linalg.solve` solves the linear system; its first p entries are the weights c_i (the last one is $-\nu$). The function returns $\sum_i c_i(x_i + \beta r_i)$.

```
def solve_n8(lam, a4=0.0, mixing="anderson", tol=1e-11, limit=200):
    x = np.zeros(2 * POINTS)
    mixer = Anderson()
    guesses, history = {}, []
    for it in range(1, limit + 1):
        residual, x_out, energy, levels = iteration(x, lam, a4, guesses)
        guesses = levels
        history.append((it, residual, energy))
```

```
        if residual <= tol:
            return energy, levels, history, x
        r = x_out - x
        x = mixer.next(x, r) if mixing == "anderson" else x + 0.4 * r
    raise RuntimeError("no convergence")
```

`solve_n8` runs the loop for the coupling `lam`. It starts from the free potentials ($x = 0$), makes a new `Anderson` object, and repeats at most 200 iterations: one iteration, its levels as the next guesses, its number, residual and energy appended to `history`; if the residual is at most 10^{-11}, the energy, levels, history and potentials are returned; otherwise the next input is made by Anderson mixing or, if `mixing` is `"linear"`, by linear mixing $x + 0.4\,r$. If the loop never converges, a `RuntimeError` stops the notebook. The cell defines functions and the class only and prints nothing.

In [11], the state $N = 8$ with $+\lambda_1$.

```
params = json.loads(repository_file("Revision/kohn_sham/results/parameters.json")
                    .read_text(encoding="utf-8"))
calib = {int(c["N"]): c for c in params["couplingCalibration"]["values"]}
LAM1, LAM2 = calib[8]["lambda1"], calib[8]["lambda2"]
```

The parameters file of the record is read; `calib` is a **dictionary comprehension** that files the calibration entries under their particle number (8, 136, 688), and `LAM1`, `LAM2` are the couplings $\lambda_1 = 0.01946$ and $\lambda_2 = 0.05838$ of $N = 8$ (Section 15.2).

```
energy, levels, history, x_final = solve_n8(LAM1)
say("iteration   residual        E_KS")
for it, residual, e in history:
    say(f"{it:9d}   {residual:9.3e}   {e:.13e}")
```

The loop is run with $+\lambda_1$ and its history is printed, one line per iteration: the iteration number, the residual and the energy. Out [11] shows the residual falling from 0.1 in the first iteration to 7.5×10^{-13} in the thirteenth, and the energy settling at $-9.8684261908764 \times 10^{-4}$.

```
SUMMARY = "Revision/kohn_sham/results/ground/summary.csv"
with open(repository_file(SUMMARY), newline="", encoding="utf-8") as handle:
    ground = {row["id"]: row for row in csv.DictReader(handle)}
runs = {run["id"]: run for run in json.loads(repository_file(
    "Revision/kohn_sham/results/ground/runs.json").read_text(encoding="utf-8"))}
recorded_history = runs["N8_lamp1_a00"]["scfHistory_iteration_residual_E"]
early = max(abs(h[1] - r[1]) / r[1] for h, r in zip(history[:6], recorded_history[:6]))
```

`with open(...) as handle:` opens the record's table of ground states and closes it again after the indented block; `csv.DictReader` reads each row as a dictionary from the column names to the values, and the rows are filed under their state name. The file `runs.json` holds for every ground state the residual and energy of each iteration; `recorded_history` is that list for `N8_lamp1_a00`. `early` is the largest relative difference between this notebook's residuals and the recorded ones in the first six iterations.

```
report("E_KS of N = 8 with lambda_1", f"{energy:.15e}")
report("iterations (this notebook / record)",
       f"{len(history)} / {len(recorded_history)}")
report("largest relative difference of the first six residuals", f"{early:.1e}")
check(abs(energy - float(ground["N8_lamp1_a00"]["E_KS"])) < 1e-14
      and abs(levels[1] - float(ground["N8_lamp1_a00"]["HOMO"])) < 1e-13,
      "E_KS and HOMO of N8_lamp1_a00 reproduced", record=f"{SUMMARY}, row N8_lamp1_a00")
check(early < 1e-5, "the first six residuals equal the recorded ones within 1e-5",
      record="Revision/kohn_sham/results/ground/runs.json, N8_lamp1_a00")
check(abs(levels[1] - levels[-1]) < 1e-13, "the levels of j = +1 and j = -1 are equal")
```

The cell reports $E_{KS} = -9.868426190876385 \times 10^{-4}$, 13 iterations here and in the record, and the relative difference 3.0×10^{-7} of the first six residuals (the later residuals are differences of nearly equal numbers and depend on the order of the arithmetic, as the text cell explains). The three checks pass: the energy and the occupied level (HOMO) agree with the record within 10^{-14} and 10^{-13}, the early residuals within 10^{-5}, and the levels of the two block types are equal, as the symmetry $\sigma_3 h_j(k) \sigma_3 = h_{-j}(-k)$ demands at $k = 0$.

In [12], Anderson against linear mixing.

```
energy_lin, _, history_lin, _ = solve_n8(LAM1, mixing="linear")
fig, ax = plt.subplots()
ax.semilogy([h[0] for h in history_lin], [h[1] for h in history_lin], "s-",
            color=PALETTE[1], ms=4, lw=1.5, label="linear mixing, $\\beta = 0.4$")
ax.semilogy([h[0] for h in history], [h[1] for h in history], "o-",
            color=PALETTE[0], ms=7, lw=2.0, label="Anderson mixing (this notebook)")
ax.semilogy([r[0] for r in recorded_history], [r[1] for r in recorded_history], "x",
            color="black", ms=9, label="Anderson mixing (Rust solver, record)")
ax.axhline(1e-11, color="0.4", ls=":", lw=1.2, label="tolerance $10^{-11}$")
```

The same state is solved with linear mixing. `ax.semilogy` draws with a logarithmic vertical axis: the residual against the iteration for linear mixing (orange squares, `"s-"`), for this notebook's Anderson run (blue dots) and for the solver's recorded run (black crosses, `"x"` without a line), and a dotted line at the tolerance.

```
ax.set_xlabel("iteration")
ax.set_ylabel("residual (units of $m$)")
ax.set_title("Self-consistent loop for $N = 8$, $\\lambda = +\\lambda_1$")
ax.legend(fontsize=8)
save_figure(fig, "scf_mixing",
            "Residual of the self-consistent loop (vertical axis, logarithmic, units "
...)
report("iterations: Anderson / linear", f"{len(history)} / {len(history_lin)}")
report("|E(linear) - E(Anderson)|", f"{abs(energy_lin - energy):.1e}")
check(abs(energy_lin - energy) < 1e-12 and len(history_lin) > 2 * len(history),
      "linear mixing reaches the same energy, with more than twice the iterations")
```

`save_figure` saves Figure 15e.5. Out [12] reports 13 iterations for Anderson mixing and 47 for linear mixing, and an energy difference of 8.0×10^{-15}: both reach the same state, linear mixing with about four times the work. The check passes. In the figure the black crosses of the Rust solver sit on the blue dots.

In [13], the four couplings and the symmetry.

```
tags = {"lamp1": LAM1, "lamm1": -LAM1, "lamp2": LAM2, "lamm2": -LAM2}
results = {}
worst_e, worst_homo = 0.0, 0.0
for tag, lam in tags.items():
    e, lv, hist, xf = solve_n8(lam)
    results[tag] = (e, lv[1], xf)
    row = ground[f"N8_{tag}_a00"]
    worst_e = max(worst_e, abs(e - float(row["E_KS"])))
    worst_homo = max(worst_homo, abs(lv[1] - float(row["HOMO"])))
    say(f"{tag}: lambda {lam:+.5f}, E_KS {e:+.12e}, HOMO {lv[1]:+.12e},"
        f" {len(hist)} it.")
```

The dictionary `tags` maps the four run tags to the couplings $\pm\lambda_1$, $\pm\lambda_2$. For each, the loop is solved, the energy, the level of $j = +1$ and the final potentials are kept in `results`, the differences to the record's row (for example `N8_lamm1_a00`) are tracked, and a line is printed; the format `+.5f` always prints the sign. Out [13] shows that E_{KS} and the HOMO of $-\lambda$ are exactly the negatives of those of $+\lambda$, with 13 iterations for $\pm\lambda_1$ and 17 for $\pm\lambda_2$.

```
xf = results["lamp1"][2]
lumo = find_level(0.25, 1, "even", 0, 0.0, (MASS + xf[:POINTS]).tolist(),
                  xf[POINTS:].tolist(), 0.43)
report("LUMO of N8_lamp1_a00 (brane band at k = 0.25)", f"{lumo:.13f}")
antisym = max(abs(results["lamp1"][0] + results["lamm1"][0]),
              abs(results["lamp2"][0] + results["lamm2"][0]))
report("largest |E(+lambda) + E(-lambda)|", f"{antisym:.1e}")
```

The lowest empty level of the state with $+\lambda_1$ is the brane-band level of the first shell, $k = 0.25$, in the converged potentials; it is found with the guess 0.43 (the free gap). `antisym` is the larger of $|E(+\lambda_1) + E(-\lambda_1)|$ and $|E(+\lambda_2) + E(-\lambda_2)|$. Out [13] prints the LUMO 0.4306983508491 and the value 0.0.

```
check(worst_e < 1e-14 and worst_homo < 1e-13,
      "E_KS and HOMO of all four couplings reproduced", record=f"{SUMMARY}, rows N8")
check(abs(lumo - float(ground["N8_lamp1_a00"]["LUMO"])) < 1e-12,
      "the LUMO of N8_lamp1_a00 reproduced", record=f"{SUMMARY}, column LUMO")
check(antisym < 1e-15, "E_KS(-lambda) = -E_KS(+lambda) for N = 8")
```

The three checks pass: the four energies and levels agree with the record, the LUMO too, and the energy is odd in λ, the exact symmetry derived in Section 15.5 (the text cell before the code cell repeats the derivation). The sum is exactly zero, not merely small, because the loop for $-\lambda$ performs exactly the arithmetic of the loop for $+\lambda$ with the signs of ε, v and b reversed, and a change of sign is exact in computer arithmetic.

In [14], the self-consistent potentials.

```
fig, (left, right) = plt.subplots(1, 2, figsize=(10.0, 4.0), layout="constrained")
labels = {"lamp1": "$+\\lambda_1$", "lamm1": "$-\\lambda_1$",
```

```
          "lamp2": "$+\\lambda_2$", "lamm2": "$-\\lambda_2$"}
for colour, (tag, label) in zip(PALETTE, labels.items()):
    xf = results[tag][2]
    style = "-" if tag.startswith("lamp") else "--"
    left.plot(Y, xf[:POINTS], style, color=colour, lw=1.8, label=label)
    right.plot(Y, xf[POINTS:], style, color=colour, lw=1.8, label=label)
```

Two drawing areas side by side, named `left` and `right`. For each coupling the converged potentials are drawn: $M - m$ on the left and v on the right, solid for positive couplings and dashed for negative ones (`tag.startswith("lamp")` is true for the tags of $+\lambda$).

```
left.set_xlabel("hidden coordinate $y$")
left.set_ylabel("$M(y) - m$ (units of $m$)")
left.set_title("Mass shift")
right.set_xlabel("hidden coordinate $y$")
right.set_ylabel("$v(y)$ (units of $m$)")
right.set_title("Potential")
right.legend()
save_figure(fig, "n8_potentials",
            "The self-consistent mass shift $M(y) - m$ (left) and potential $v(y)$ "
...)
```

The axis labels and titles, and `save_figure` for Figure 15e.6. The student should see the potential $v = -\lambda n/16$ grow toward the tip roughly like e^{-4y}: the zero mode is e^{y}, so its coordinate density is e^{2y}, and dividing by the proper volume factor e^{6y} gives e^{-4y}. This growth toward the tip is why the interacting $N = 8$ results depend strongly on the cutoff L (Section 15.2, the paragraph on the cutoff). The mass shift is smaller, because the scalar density of the zero modes vanishes without interaction ($b = 0$) and is created only by the interaction itself.

```
plus, minus = results["lamp1"][2], results["lamm1"][2]  # potentials x of +-lambda_1
mirror = max(float(np.max(np.abs(plus[:POINTS] - minus[:POINTS]))),
             float(np.max(np.abs(plus[POINTS:] + minus[POINTS:]))))
report("largest violation of the potential symmetry", f"{mirror:.1e}")
check(mirror < 1e-12, "M - m is even and v is odd under lambda -> -lambda")
```

The symmetry of Section 15.5 predicts that $M - m$ is the same for $\pm\lambda$ and v changes sign. `mirror` is the larger of the largest $|(M-m)_+ - (M-m)_-|$ and the largest $|v_+ + v_-|$. Out [14] prints 0.0 and PASS; in the figure the dashed curves of the mass shift lie on the solid ones.

In [15], the last check.

```
NAMES = ["phase_function", "orbitals", "rk4_convergence", "brane_band", "scf_mixing",
         "n8_potentials"]
missing = [name for number, name in enumerate(NAMES, start=1)
           if not output_file(f"{FIGURE_FOLDER}/15e_{number}_{name}.png").is_file()]
check(missing == [], "every figure file of this notebook exists")
all_checks_passed()
```

`NAMES` lists the six figure names in order. `enumerate(NAMES, start=1)` pairs each name with its number 1, 2, ...; the list comprehension with `if not ...` collects the names whose file does not

exist. The check requires that list to be empty, and `all_checks_passed()` prints the last line, ALL 18 CHECKS PASSED (notebook 15e).

15.10 The Rust solver and its canonical matrix

Notebook 15e showed the method on the smallest state. The Revision record computes every state of the canonical matrix with a compiled program, the **Rust solver** `revision_ks_solver`, whose source is the folder `Revision/kohn_sham/solver` of the repository. Rust is a programming language whose programs are translated once into machine code by its tool cargo and then run much faster than Python; the solver needs no packages from outside the repository, so cargo downloads nothing.

What is in the program. The source is split into modules, one file each in `Revision/kohn_sham/solver/src`:

- `theory.rs` reads the theory file `Revision/kohn_sham/ks-theory.json` and the gamma matrices `Revision/algebra/gammas.json` and checks again, in floating point, that the block basis of Chapter 14 really makes every operator of the problem block diagonal (check block_reduction_numeric);
- `shoot.rs` holds the shooting with the Pruefer angle and the safeguarded Newton root of Section 15.3;
- `scf.rs` holds the label sets, the aufbau, the densities and the self-consistent loop with Anderson mixing of Sections 15.4 and 15.5;
- `mermin.rs` finds the chemical potential at a temperature (Section 15.26);
- `analysis.rs` computes the energy-momentum tensor, its identities, the adiabaticity measure and the particle-hole lists;
- `spectrum.rs` computes the free spectra and their exact checks;
- `runs.rs` runs the whole canonical matrix;
- `json.rs`, `sha256.rs`, `report.rs` and `model.rs` write the results deterministically, compute fingerprints, collect the checks and hold the parameters.

The two ways to run it. The command `revision_ks_solver all` computes the whole canonical matrix of Section 15.2 and writes it into a folder of results. For each of the 75 ground states it solves the state itself, the same state at the four neighbouring slices $a_{4,0} \pm \delta$ and $a_{4,0} \pm 2\delta$ with $\delta = 0.002$ (for the derivatives along the history), the first excited state (Delta-SCF), the partner state of the rescaling identity (for the 60 states with $a_{4,0} > 0$), and the variant with the exact Fock exchange (for the 60 states with $\lambda \neq 0$); for each of the 135 thermal states it solves the state and its four neighbours at the temperatures $T \pm 0.01T$ and $T \pm 0.02T$ (for the temperature derivatives). It then evaluates its 42 checks, prints each as a line PASS - name or FAIL - name on its error stream, writes them into a report, and prints SUCCESS or FAILURE as the last line of its output stream. The command `revision_ks_solver single` solves one state with chosen parameters (m, λ, $a_{4,0}$, N and, if wanted, T) and writes its levels, energies and energy-momentum integrals as a JSON file and, if wanted, its profiles as a CSV file; Notebooks 15b and 15d use it.

The results. The folder `Revision/kohn_sham/results` holds the canonical matrix: `parameters.json` (all parameters and the calibration of Section 15.2), `manifest.json` (the list of every result file with its sha256 fingerprint, a 64-digit number computed from the bytes of a file, so that two files with the same fingerprint are identical), `spectrum/` (the free spectra), `ground/` (the 75 ground states: a summary table, the history of every self-consistent loop, the level tables, the profiles of the densities and the energy-momentum tensor at the 151 points $y = -3, -2.98, \ldots, 0$, and the integrals of the tensor), `excited/` (Delta-SCF and the particle-hole excitations), `adiabatic/` (Section 15.21), `rescaling/`, `exx/` (the exact-Fock variant) and `thermo/` (the 135 thermal states). Every number is written with 16 significant digits and no time stamp or path, so that a second run writes the same bytes.

How the record checks itself. Three reports belong to the solver. `Revision/kohn_sham/reports/ks-rust-solver.json` holds the 42 checks of the run itself, all PASS: the theory input, the free spectra (exact levels, zero mode, band slope, block symmetries, labels, tip angle, rescaling), every state (convergence, particle number, boundary conditions, the two energy forms, the energy-momentum identities, closed shells, completeness of the label sets), the derivatives along the history, the excited states, the exact-Fock variant, the thermodynamics and the chemical potential. `Revision/kohn_sham/reports/ks-rust-determinism.json` (14 checks, all PASS) compares a second run with the canonical one (all 244 files, the 243 result files and the manifest, byte-identical; check repeat_byte_identical) and a **refined run** with twice the RK4 steps and ten times smaller tolerances, against tolerances fixed before the comparison (10^{-8} for levels, energies and thermodynamics, 10^{-6} for profiles and derived quantities): for example E_{KS} agrees to 1.9×10^{-12} relative (check refined_ground_energies) and 23724 levels agree label by label to $2.1 \times 10^{-9}\, m$ (check refined_eigenvalues). `Revision/kohn_sham/reports/ks-rust-mermin-roots.json` compares every chemical potential with a 40-digit root (Section 15.26). An independent cross-check by a second program written in Python is the subject of Chapter 16.

Threads. The solver distributes independent states over the processor cores (at most 22 threads) and merges the results in a fixed order, so the number of threads does not change any output byte. The record's run of the canonical matrix took 78.1 s on an idle machine with 22 threads (`Revision/kohn_sham/solver/README.md`, Timings); the whole Notebook 15a took 164 s and 232 s in its two recorded runs on the machine that built the book, while other programs were running (section 4.5 of `Revision/textbook/notebooks/15a_canonical_matrix.PROVENANCE.md`).

15.11 Example: running the canonical matrix (Notebook 15a)

Notebook 15a builds the solver with cargo on the student's computer, runs `revision_ks_solver all` into a folder that git ignores, and checks the new run against the committed record in three ways: the solver's own 42 checks must all pass and match the record's list; the new run must write the same 243 result files (and on the computer that built the book they are byte-identical); and the key numbers must agree within the tolerances that the record fixed in advance. Then it reads the new results and draws eight figures: the levels of $N = 136$ along the history (Figure 15a.1), the gaps (Figure 15a.2), the orbital relaxation of Delta-SCF (Figure 15a.3), the total energies and the interaction shifts (Figure 15a.4), the densities (Figure 15a.5), the self-consistent potentials (Figure 15a.6), the convergence of the self-consistent loop (Figure 15a.7) and the particle-hole excitations (Figure 15a.8). It needs Rust (the run instructions below explain how to install it), takes two to four minutes on a computer with many cores and up to about ten minutes on a laptop, and ends with ALL 25 CHECKS PASSED (notebook 15a).

What to look for: in Figure 15a.1 the blue brane-band levels that fall from slice to slice while the black levels at $k = 0$ stay flat; in Figure 15a.2 the gaps that fall almost, but not quite, like the dashed lines $e^{-a_{4,0}}$; in Figure 15a.5 that the particles sit near the brane although the proper density is largest at the tip.

15.12 How to run Notebook 15a

Step 1. What this notebook does and what it needs.

Notebook 15a (Running the Rust Kohn-Sham solver over the canonical matrix) is the file `Revision/textbook/notebooks/15a_canonical_matrix.ipynb` of the repository Dirac_claude. It builds the Rust Kohn-Sham solver of the repository with cargo (a full build of about a minute when the program is missing, a second when it is up to date), runs it over the whole canonical matrix (75 ground states and 135 thermal states of the Kohn-Sham gas of dirac16complex along the deflating history), checks that the new results agree with the committed Revision record within tolerances fixed in advance, and draws the Kohn-Sham levels, the gaps, the energies, the densities, the self-consistent potentials, the convergence of the self-consistent loop and the particle-hole excitations. The solver writes its raw output (about 6 MB) into the folder `Revision/kohn_sham/solver/target/textbook_15a`, which git ignores. It needs a computer with Windows 11, macOS or Linux, an internet connection for the installation, the program Git, and Python 3.12 or newer (the notebooks were built with Python 3.14.5) with these packages at exactly these versions: numpy 2.4.6, sympy 1.14.0, mpmath 1.3.0, matplotlib 3.11.0, jupyterlab 4.4.10, nbformat 5.10.4, nbclient 0.10.2, ipykernel 7.1.0 and nbconvert 7.16.6. The notebook itself imports numpy and matplotlib; the other packages run Jupyter, the program that shows and runs notebooks. It also needs Rust (the program cargo, version 1.91.1 or newer), because it runs the Rust program revision_ks_solver, which is part of the repository and is built on your computer.

Step 2. Install Git and Python (once per computer).

A terminal is the window in which you type commands: on Windows the app Windows PowerShell (or Terminal), on macOS the app Terminal (it runs the shell zsh), on Linux any terminal (it runs the shell bash). Type every command of this section into a terminal exactly as printed, one line at a time, and press Enter after each line.

Windows: download Git from https://git-scm.com/download/win and install it with the default choices. Download Python from https://www.python.org/downloads/ and run the installer; in its first window tick the box "Add python.exe to PATH" before you click "Install Now".

macOS: download Python from https://www.python.org/downloads/ and run the installer. Then open the app Terminal and run this command, which installs Git and the compiler tools:

macOS (zsh):

```
xcode-select --install
```

Linux (Debian or Ubuntu; other distributions have packages of the same names): run these two commands:

Linux (bash):

```
sudo apt update
sudo apt install git python3 python3-venv
```

Then close the terminal and open a NEW one (a terminal opened before the installation does not know the new programs), and check the version of Python; it must print 3.12 or a higher number:

Windows (PowerShell):

```
py -3 --version
```

macOS (zsh) and Linux (bash):

```
python3 --version
```

If an older Linux prints a lower number (Ubuntu 22.04 has Python 3.10), install Python 3.12 with the following three commands, and in Step 3 type `python3.12` instead of `python3` in the command that creates the environment:

Linux (bash), only when the version is too low:

```
sudo add-apt-repository ppa:deadsnakes/ppa
sudo apt update
sudo apt install python3.12 python3.12-venv
```

Step 3. Get the repository and install the packages (once per computer).

The commands below download the repository (a few hundred megabytes; the folder then needs up to about 1 GB of disk space) into the folder Dirac_claude inside your home folder, create a private Python environment in the folder dirac-book-env inside your home folder (a private environment is a folder with its own copy of Python and of the packages, so that nothing else on your computer is changed), activate it (from then on the commands `python` and `jupyter` typed in this terminal are those of the environment, and the prompt starts with (dirac-book-env)), and install the packages at the pinned versions (this downloads about 90 MB and takes a few minutes; the environment takes about 400 MB of disk space). If you have done this step before, for this or for another notebook, skip it and go to Step 4; to get the newest version of the repository, run `git pull` in the repository folder after Step 4.

Windows (PowerShell):

```
cd $HOME
git clone https://github.com/once-ere/Dirac_claude.git
py -3 -m venv "$HOME\dirac-book-env"
Set-ExecutionPolicy -ExecutionPolicy RemoteSigned -Scope Process -Force
& "$HOME\dirac-book-env\Scripts\Activate.ps1"
python -m pip install --upgrade pip
python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
```

The line with `Set-ExecutionPolicy` allows PowerShell to run the activation script in this one window only; it changes nothing permanently.

macOS (zsh):

```
cd ~
git clone https://github.com/once-ere/Dirac_claude.git
python3 -m venv ~/dirac-book-env
source ~/dirac-book-env/bin/activate
python -m pip install --upgrade pip
python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
```

Linux (bash):

```
cd ~
git clone https://github.com/once-ere/Dirac_claude.git
python3 -m venv ~/dirac-book-env
source ~/dirac-book-env/bin/activate
python -m pip install --upgrade pip
python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
```

Step 4. In every new terminal: activate the environment and go into the repository folder.

Every later step starts in the repository folder with the environment active. Run these lines whenever you open a new terminal (they do no harm if the environment is already active):

Windows (PowerShell):

```
Set-ExecutionPolicy -ExecutionPolicy RemoteSigned -Scope Process -Force
& "$HOME\dirac-book-env\Scripts\Activate.ps1"
cd "$HOME\Dirac_claude"
```

macOS (zsh) and Linux (bash):

```
source ~/dirac-book-env/bin/activate
cd ~/Dirac_claude
```

Step 5. Install Rust and build the Rust program (Rust once per computer, the build once per program).

Windows: download `rustup-init.exe` from https://rustup.rs, run it and accept the default choices; if it reports that the Visual Studio C++ Build Tools are missing, let it install them (or install the workload "Desktop development with C++" from https://visualstudio.microsoft.com/visual-cpp-build-tools/ and run `rustup-init.exe` again). macOS and Linux: run the command below and

accept the default choice (on Linux first run `sudo apt install build-essential`, which provides the linker that Rust needs).

macOS (zsh) and Linux (bash):

```
curl --proto "=https" --tlsv1.2 -sSf https://sh.rustup.rs | sh
```

Then close the terminal, open a new one, do Step 4 again, and check the version of cargo; it must print 1.91.1 or a newer version:

Windows, macOS and Linux:

```
cargo --version
```

Build the program with the following command, in the repository folder (the same command on all three systems):

Windows, macOS and Linux:

```
cargo build --release --manifest-path Revision/kohn_sham/solver/Cargo.toml
```

The first build takes about 1 minute; later builds reuse the result and take a few seconds. The program is then the file `Revision/kohn_sham/solver/target/release/revision_ks_solver` (on Windows with the ending `.exe`). The notebook runs the same build command itself before it uses the program (it takes a second when the program is up to date), so the notebook also works if you skip this build; building here first shows any problem with Rust before the notebook starts.

Step 6. Run the notebook in JupyterLab.

In the repository folder, with the environment active, run these two lines (the first one goes into the folder of the notebooks):

Windows, macOS and Linux:

```
cd Revision/textbook/notebooks
jupyter lab 15a_canonical_matrix.ipynb
```

JupyterLab opens in your web browser and shows the notebook (if no browser window opens, copy the address that starts with `http://localhost:8888/lab` from the terminal into the address bar of your browser). The name at the top right of the notebook must read Python 3 (ipykernel). Choose the menu Run > Run All Cells. While a cell runs, the label to its left shows `[*]`; when it has finished, the label shows a number. The notebook has finished when the last code cell shows a number; this takes about 10 minutes on a typical laptop. Scroll to the end and compare the last printed lines with the lines in the step "What the notebook writes and what you must see" below. To keep the results, save the notebook (menu File > Save Notebook). To stop JupyterLab, choose the menu File > Shut Down, or press Ctrl+C twice in the terminal.

Step 7. Or run the notebook without a browser (headless).

In the repository folder, with the environment active, run:

Windows, macOS and Linux:

```
cd Revision/textbook/notebooks
jupyter nbconvert --to notebook --execute --inplace 15a_canonical_matrix.ipynb
```

This runs every cell from the top to the bottom and saves the results into the notebook file. A failed check stops it with an error message that contains AssertionError and the name of the check. If the command ends with a line that starts with `[NbConvertApp] Writing` and shows no error, every check passed; open the notebook with `jupyter lab 15a_canonical_matrix.ipynb` (in the same folder, without running the cells again) to read the printed lines and see the figures.

Step 8. What the notebook writes and what you must see.

The notebook writes (or overwrites) these files:

- `Revision/textbook/figures/15a.captions.json`
- `Revision/textbook/figures/15a_1_levels_history.png`
- `Revision/textbook/figures/15a_2_gaps_history.png`
- `Revision/textbook/figures/15a_3_delta_scf.png`
- `Revision/textbook/figures/15a_4_energy_history.png`
- `Revision/textbook/figures/15a_5_densities.png`
- `Revision/textbook/figures/15a_6_potentials.png`
- `Revision/textbook/figures/15a_7_scf_convergence.png`
- `Revision/textbook/figures/15a_8_particle_hole.png`

It changes no other file of the repository except the Rust build folder `target` next to each `Cargo.toml` it builds (inside it the notebook keeps the raw output of its program runs in `Revision/kohn_sham/solver/target/textbook_15a`, which git ignores); running it headless or saving it in JupyterLab also rewrites the notebook file itself. It does not use the internet while it runs. The files it writes are the same files that are stored in the repository (on another computer a figure may differ in a few bytes, which is harmless). To get the stored versions back, run this command in the repository folder (it also undoes every change you made yourself in the folder Revision/textbook):

Windows, macOS and Linux:

```
git checkout -- Revision/textbook
```

Every check of the notebook prints a line that starts with PASS. At the end of the notebook (the output of its last code cell) you must see exactly these lines:

```
PASS every figure file of this notebook exists
ALL 25 CHECKS PASSED (notebook 15a)
```

and the notebook must show 8 figures below the cells that draw them.

Step 9. If something goes wrong.

- "ModuleNotFoundError: No module named ..." in the notebook: JupyterLab was started without the environment. Stop it (menu File > Shut Down), do Step 4, and start it again. If the error remains, another Python installation has registered its own kernel called python3; with the environment active, run the following command and start JupyterLab again:

```
python -m ipykernel install --user --name python3
```

- "FileNotFoundError: The repository folder was not found": the notebook was opened from a copy outside the repository. Open the file `Revision/textbook/notebooks/15a_canonical_matrix.ipynb` inside the folder Dirac_claude.
- "fatal: destination path 'Dirac_claude' already exists" in Step 3: the repository was downloaded before; skip the line with `git clone`.
- Windows: "running scripts is disabled on this system": run the line with `Set-ExecutionPolicy` and then the activation line again. "py is not recognized": use `python` instead of `py -3`; "python is not recognized": install Python again and tick "Add python.exe to PATH".
- Linux: "ensurepip is not available" when the environment is created: run `sudo apt install python3-venv` and repeat Step 3.
- "jupyter is not recognized" or "command not found: jupyter": the environment is not active; do Step 4. If the environment is active and the message stays, the programs jupyter-lab and jupyter-nbconvert are not in the folders where the terminal looks for programs (`python -m jupyter` does not help then: it has to find the same programs). Start them through Python itself, in the folder of the notebook: the first command below does what `jupyter lab` does, the second what the headless command does:

```
python -m jupyterlab 15a_canonical_matrix.ipynb
python -m nbconvert --execute --inplace 15a_canonical_matrix.ipynb
```

- Windows: the headless run prints a RuntimeWarning that mentions the "Proactor event loop" and zmq: this is a message of the package pyzmq, not an error; the run continues normally.
- A red box with "Matplotlib is building the font cache; this may take a moment." in the first run after the installation: this is a message, not an error; the run continues and the message does not come again.
- An AssertionError names a check that failed: choose the menu Kernel > Restart Kernel and Run All Cells; if it fails again, install the packages again with the pip commands of Step 3, because a different package version can change the last digits of a result.
- "cargo is not recognized" or "command not found: cargo" or "cargo was not found": open a new terminal after installing Rust, do Step 4 again, and start JupyterLab from this terminal.
- "linker link.exe not found" (Windows) or "linker cc not found" (Linux): install the C++ Build Tools (Windows) or build-essential (Linux) as described in Step 5 and build again.

- The cell that runs the canonical matrix shows the label with the star for several minutes: this is normal. The solver computes 210 states and uses up to 22 processor cores; on the computer that built the notebook (22 cores) the whole notebook takes two to four minutes, and on a computer with 4 cores it can need up to about 10 minutes. Wait until the label shows a number.
- An AssertionError names one of the comparisons with the record: the notebook prints the largest difference just above the error. Differences far below the tolerance are rounding effects of another computer; a larger difference means that the solver or its input files were changed. Get the stored versions back and run the notebook again.

```
git checkout -- Revision/kohn_sham
```

- You want the disk space of the solver output back: the folder `Revision/kohn_sham/solver/target/textbook_15a` holds only the raw output of the last run (ignored by git); delete it at any time, the notebook writes it again.

15.13 Notebook 15a: complete text

This section prints the complete text of the notebook file `Revision/textbook/notebooks/15a_canonical_matrix.ipynb`: every cell in order, with the output that the stored, executed notebook holds. A text cell (Jupyter calls it a markdown cell) is printed in a frame after the label Text cell. A code cell is printed after the label In [k], where k is the number that Jupyter gives the cell when it runs it; the text that the cell prints follows after the label Out [k], and every figure that the cell draws follows as a figure with its caption.

Text cell:

```
## 1. What this notebook computes

This notebook runs the **Rust Kohn-Sham solver** of the repository over its whole
**canonical matrix**: the Kohn-Sham states of the fermion field dirac16complex in
the author's primordial gravitational field, for three particle numbers, five
couplings and five instants of the deflating history (75 ground states), and for
135 states at three temperatures. Then it

- checks that the solver reports every one of its own checks as PASS (the
  committed record holds 42 of them);
- compares every new result with the committed Revision record (the folder
  Revision/kohn_sham/results), number by number, with tolerances that were fixed in
  advance;
- prints the energies and gaps of the ground states along the history;
- draws eight figures: the Kohn-Sham levels along the history, the gaps, the
  Delta-SCF excitation energies, the total energies, the densities, the
  self-consistent potentials, the convergence of the self-consistent loop and the
  particle-hole excitations.

The run takes two to four minutes on a computer with many processor cores
(up to about ten minutes on a laptop). Everything it writes outside the folder of
```

the figures goes into the Rust build folder
‘Revision/kohn_sham/solver/target/textbook_15a‘, which git ignores.

Text cell:

```
## 2. How to run this notebook

**Step 1. What this notebook does and what it needs.**

Notebook 15a (Running the Rust Kohn-Sham solver over the canonical matrix) is the file
‘Revision/textbook/notebooks/15a_canonical_matrix.ipynb‘ of the repository Dirac_claude.
It builds the Rust Kohn-Sham solver of the repository with cargo (a full build of about a
minute when the program is missing, a second when it is up to date), runs it over the
whole canonical matrix (75 ground states and 135 thermal states of the Kohn-Sham gas of
dirac16complex along the deflating history), checks that the new results agree with the
committed Revision record within tolerances fixed in advance, and draws the Kohn-Sham
levels, the gaps, the energies, the densities, the self-consistent potentials, the
convergence of the self-consistent loop and the particle-hole excitations. The solver
writes its raw output (about 6 MB) into the folder
‘Revision/kohn_sham/solver/target/textbook_15a‘, which git ignores. It needs a computer
with Windows 11, macOS or Linux, an internet connection for the installation, the program
Git, and Python 3.12 or newer (the notebooks were built with Python 3.14.5) with these
packages at exactly these versions: numpy 2.4.6, sympy 1.14.0, mpmath 1.3.0, matplotlib
3.11.0, jupyterlab 4.4.10, nbformat 5.10.4, nbclient 0.10.2, ipykernel 7.1.0 and
nbconvert 7.16.6. The notebook itself imports numpy and matplotlib; the other packages
run Jupyter, the program that shows and runs notebooks. It also needs Rust (the program
cargo, version 1.91.1 or newer), because it runs the Rust program revision_ks_solver,
which is part of the repository and is built on your computer.

**Step 2. Install Git and Python (once per computer).**

A terminal is the window in which you type commands: on Windows the app Windows
PowerShell (or Terminal), on macOS the app Terminal (it runs the shell zsh), on Linux any
terminal (it runs the shell bash). Type every command of this section into a terminal
exactly as printed, one line at a time, and press Enter after each line.

Windows: download Git from https://git-scm.com/download/win and install it with the
default choices. Download Python from https://www.python.org/downloads/ and run the
installer; in its first window tick the box "Add python.exe to PATH" before you click
"Install Now".

macOS: download Python from https://www.python.org/downloads/ and run the installer. Then
open the app Terminal and run this command, which installs Git and the compiler tools:

macOS (zsh):

    xcode-select --install

Linux (Debian or Ubuntu; other distributions have packages of the same names): run these
two commands:

Linux (bash):
```

```
    sudo apt update
    sudo apt install git python3 python3-venv
```

Then close the terminal and open a NEW one (a terminal opened before the installation does not know the new programs), and check the version of Python; it must print 3.12 or a higher number:

Windows (PowerShell):

```
    py -3 --version
```

macOS (zsh) and Linux (bash):

```
    python3 --version
```

If an older Linux prints a lower number (Ubuntu 22.04 has Python 3.10), install Python 3.12 with the following three commands, and in Step 3 type ‘python3.12‘ instead of ‘python3‘ in the command that creates the environment:

Linux (bash), only when the version is too low:

```
    sudo add-apt-repository ppa:deadsnakes/ppa
    sudo apt update
    sudo apt install python3.12 python3.12-venv
```

Step 3. Get the repository and install the packages (once per computer).

The commands below download the repository (a few hundred megabytes; the folder then needs up to about 1 GB of disk space) into the folder Dirac_claude inside your home folder, create a private Python environment in the folder dirac-book-env inside your home folder (a private environment is a folder with its own copy of Python and of the packages, so that nothing else on your computer is changed), activate it (from then on the commands ‘python‘ and ‘jupyter‘ typed in this terminal are those of the environment, and the prompt starts with (dirac-book-env)), and install the packages at the pinned versions (this downloads about 90 MB and takes a few minutes; the environment takes about 400 MB of disk space). If you have done this step before, for this or for another notebook, skip it and go to Step 4; to get the newest version of the repository, run ‘git pull‘ in the repository folder after Step 4.

Windows (PowerShell):

```
    cd $HOME
    git clone https://github.com/once-ere/Dirac_claude.git
    py -3 -m venv "$HOME\dirac-book-env"
    Set-ExecutionPolicy -ExecutionPolicy RemoteSigned -Scope Process -Force
    & "$HOME\dirac-book-env\Scripts\Activate.ps1"
    python -m pip install --upgrade pip
    python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
    python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
    python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
```

The line with ‘Set-ExecutionPolicy‘ allows PowerShell to run the activation script in this one window only; it changes nothing permanently.

macOS (zsh):

```
cd ~
git clone https://github.com/once-ere/Dirac_claude.git
python3 -m venv ~/dirac-book-env
source ~/dirac-book-env/bin/activate
python -m pip install --upgrade pip
python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
```

Linux (bash):

```
cd ~
git clone https://github.com/once-ere/Dirac_claude.git
python3 -m venv ~/dirac-book-env
source ~/dirac-book-env/bin/activate
python -m pip install --upgrade pip
python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
```

Step 4. In every new terminal: activate the environment and go into the repository folder.

Every later step starts in the repository folder with the environment active. Run these lines whenever you open a new terminal (they do no harm if the environment is already active):

Windows (PowerShell):

```
Set-ExecutionPolicy -ExecutionPolicy RemoteSigned -Scope Process -Force
& "$HOME\dirac-book-env\Scripts\Activate.ps1"
cd "$HOME\Dirac_claude"
```

macOS (zsh) and Linux (bash):

```
source ~/dirac-book-env/bin/activate
cd ~/Dirac_claude
```

Step 5. Install Rust and build the Rust program (Rust once per computer, the build once per program).

Windows: download ‘rustup-init.exe‘ from https://rustup.rs, run it and accept the default choices; if it reports that the Visual Studio C++ Build Tools are missing, let it install them (or install the workload "Desktop development with C++" from https://visualstudio.microsoft.com/visual-cpp-build-tools/ and run ‘rustup-init.exe‘ again). macOS and Linux: run the command below and accept the default choice (on Linux first run ‘sudo apt install build-essential‘, which provides the linker that Rust needs).

macOS (zsh) and Linux (bash):

```
curl --proto "=https" --tlsv1.2 -sSf https://sh.rustup.rs | sh
```

Then close the terminal, open a new one, do Step 4 again, and check the version of cargo; it must print 1.91.1 or a newer version:

Windows, macOS and Linux:

```
cargo --version
```

Build the program with the following command, in the repository folder (the same command on all three systems):

Windows, macOS and Linux:

```
cargo build --release --manifest-path Revision/kohn_sham/solver/Cargo.toml
```

The first build takes about 1 minute; later builds reuse the result and take a few seconds. The program is then the file ‘Revision/kohn_sham/solver/target/release/revision_ks_solver‘ (on Windows with the ending ‘.exe‘). The notebook runs the same build command itself before it uses the program (it takes a second when the program is up to date), so the notebook also works if you skip this build; building here first shows any problem with Rust before the notebook starts.

Step 6. Run the notebook in JupyterLab.

In the repository folder, with the environment active, run these two lines (the first one goes into the folder of the notebooks):

Windows, macOS and Linux:

```
cd Revision/textbook/notebooks
jupyter lab 15a_canonical_matrix.ipynb
```

JupyterLab opens in your web browser and shows the notebook (if no browser window opens, copy the address that starts with ‘http://localhost:8888/lab‘ from the terminal into the address bar of your browser). The name at the top right of the notebook must read Python 3 (ipykernel). Choose the menu Run > Run All Cells. While a cell runs, the label to its left shows ‘[*]‘; when it has finished, the label shows a number. The notebook has finished when the last code cell shows a number; this takes about 10 minutes on a typical laptop. Scroll to the end and compare the last printed lines with the lines in the step "What the notebook writes and what you must see" below. To keep the results, save the notebook (menu File > Save Notebook). To stop JupyterLab, choose the menu File > Shut Down, or press Ctrl+C twice in the terminal.

Step 7. Or run the notebook without a browser (headless).

In the repository folder, with the environment active, run:

Windows, macOS and Linux:

```
cd Revision/textbook/notebooks
jupyter nbconvert --to notebook --execute --inplace 15a_canonical_matrix.ipynb
```

This runs every cell from the top to the bottom and saves the results into the notebook file. A failed check stops it with an error message that contains AssertionError and the name of the check. If the command ends with a line that starts with ‘[NbConvertApp]

Writing‘ and shows no error, every check passed; open the notebook with ‘jupyter lab 15a_canonical_matrix.ipynb‘ (in the same folder, without running the cells again) to read the printed lines and see the figures.

Step 8. What the notebook writes and what you must see.

The notebook writes (or overwrites) these files:

- ‘Revision/textbook/figures/15a.captions.json‘
- ‘Revision/textbook/figures/15a_1_levels_history.png‘
- ‘Revision/textbook/figures/15a_2_gaps_history.png‘
- ‘Revision/textbook/figures/15a_3_delta_scf.png‘
- ‘Revision/textbook/figures/15a_4_energy_history.png‘
- ‘Revision/textbook/figures/15a_5_densities.png‘
- ‘Revision/textbook/figures/15a_6_potentials.png‘
- ‘Revision/textbook/figures/15a_7_scf_convergence.png‘
- ‘Revision/textbook/figures/15a_8_particle_hole.png‘

It changes no other file of the repository except the Rust build folder ‘target‘ next to each ‘Cargo.toml‘ it builds (inside it the notebook keeps the raw output of its program runs in ‘Revision/kohn_sham/solver/target/textbook_15a‘, which git ignores); running it headless or saving it in JupyterLab also rewrites the notebook file itself. It does not use the internet while it runs. The files it writes are the same files that are stored in the repository (on another computer a figure may differ in a few bytes, which is harmless). To get the stored versions back, run this command in the repository folder (it also undoes every change you made yourself in the folder Revision/textbook):

Windows, macOS and Linux:

```
git checkout -- Revision/textbook
```

Every check of the notebook prints a line that starts with PASS. At the end of the notebook (the output of its last code cell) you must see exactly these lines:

```
PASS every figure file of this notebook exists
ALL 25 CHECKS PASSED (notebook 15a)
```

and the notebook must show 8 figures below the cells that draw them.

Step 9. If something goes wrong.

- "ModuleNotFoundError: No module named ..." in the notebook: JupyterLab was started without the environment. Stop it (menu File > Shut Down), do Step 4, and start it again. If the error remains, another Python installation has registered its own kernel called python3; with the environment active, run the following command and start JupyterLab again:

  ```
  python -m ipykernel install --user --name python3
  ```

- "FileNotFoundError: The repository folder was not found": the notebook was opened from a copy outside the repository. Open the file ‘Revision/textbook/notebooks/15a_canonical_matrix.ipynb‘ inside the folder Dirac_claude.
- "fatal: destination path ’Dirac_claude’ already exists" in Step 3: the repository was

  downloaded before; skip the line with ‘git clone‘.
- Windows: "running scripts is disabled on this system": run the line with ‘Set-ExecutionPolicy‘ and then the activation line again. "py is not recognized": use ‘python‘ instead of ‘py -3‘; "python is not recognized": install Python again and tick "Add python.exe to PATH".
- Linux: "ensurepip is not available" when the environment is created: run ‘sudo apt install python3-venv‘ and repeat Step 3.
- "jupyter is not recognized" or "command not found: jupyter": the environment is not active; do Step 4. If the environment is active and the message stays, the programs jupyter-lab and jupyter-nbconvert are not in the folders where the terminal looks for programs (‘python -m jupyter‘ does not help then: it has to find the same programs). Start them through Python itself, in the folder of the notebook: the first command below does what ‘jupyter lab‘ does, the second what the headless command does:

```
python -m jupyterlab 15a_canonical_matrix.ipynb
python -m nbconvert --execute --inplace 15a_canonical_matrix.ipynb
```

- Windows: the headless run prints a RuntimeWarning that mentions the "Proactor event loop" and zmq: this is a message of the package pyzmq, not an error; the run continues normally.
- A red box with "Matplotlib is building the font cache; this may take a moment." in the first run after the installation: this is a message, not an error; the run continues and the message does not come again.
- An AssertionError names a check that failed: choose the menu Kernel > Restart Kernel and Run All Cells; if it fails again, install the packages again with the pip commands of Step 3, because a different package version can change the last digits of a result.
- "cargo is not recognized" or "command not found: cargo" or "cargo was not found": open a new terminal after installing Rust, do Step 4 again, and start JupyterLab from this terminal.
- "linker link.exe not found" (Windows) or "linker cc not found" (Linux): install the C++ Build Tools (Windows) or build-essential (Linux) as described in Step 5 and build again.
- The cell that runs the canonical matrix shows the label with the star for several minutes: this is normal. The solver computes 210 states and uses up to 22 processor cores; on the computer that built the notebook (22 cores) the whole notebook takes two to four minutes, and on a computer with 4 cores it can need up to about 10 minutes. Wait until the label shows a number.
- An AssertionError names one of the comparisons with the record: the notebook prints the largest difference just above the error. Differences far below the tolerance are rounding effects of another computer; a larger difference means that the solver or its input files were changed. Get the stored versions back and run the notebook again.

```
git checkout -- Revision/kohn_sham
```

- You want the disk space of the solver output back: the folder ‘Revision/kohn_sham/solver/target/textbook_15a‘ holds only the raw output of the last run (ignored by git); delete it at any time, the notebook writes it again.

The first code cell below (the set-up cell) repeats these instructions as comments; then it imports the packages, finds the repository folder and defines the helpers ‘save_figure‘ (saves a figure and shows it), ‘check‘ (stops with an AssertionError when a check fails, prints a PASS line when it passes), ‘report‘ (prints a key number as a RESULT line) and ‘all_checks_passed‘ (prints the last line).

In [1]:

```
# HOW TO RUN NOTEBOOK 15a (the complete instructions)
#
# STEP 1. WHAT THIS NOTEBOOK DOES AND WHAT IT NEEDS.
#
# Notebook 15a (Running the Rust Kohn-Sham solver over the canonical matrix) is the file
# Revision/textbook/notebooks/15a_canonical_matrix.ipynb of the repository Dirac_claude.
# It builds the Rust Kohn-Sham solver of the repository with cargo (a full build of about
# a minute when the program is missing, a second when it is up to date), runs it over the
# whole canonical matrix (75 ground states and 135 thermal states of the Kohn-Sham gas of
# dirac16complex along the deflating history), checks that the new results agree with the
# committed Revision record within tolerances fixed in advance, and draws the Kohn-Sham
# levels, the gaps, the energies, the densities, the self-consistent potentials, the
# convergence of the self-consistent loop and the particle-hole excitations. The solver
# writes its raw output (about 6 MB) into the folder
# Revision/kohn_sham/solver/target/textbook_15a, which git ignores. It needs a computer
# with Windows 11, macOS or Linux, an internet connection for the installation, the
# program Git, and Python 3.12 or newer (the notebooks were built with Python 3.14.5)
# with these packages at exactly these versions: numpy 2.4.6, sympy 1.14.0, mpmath 1.3.0,
# matplotlib 3.11.0, jupyterlab 4.4.10, nbformat 5.10.4, nbclient 0.10.2, ipykernel 7.1.0
# and nbconvert 7.16.6. The notebook itself imports numpy and matplotlib; the other
# packages run Jupyter, the program that shows and runs notebooks. It also needs Rust
# (the program cargo, version 1.91.1 or newer), because it runs the Rust program
# revision_ks_solver, which is part of the repository and is built on your computer.
#
# STEP 2. INSTALL GIT AND PYTHON (ONCE PER COMPUTER).
#
# A terminal is the window in which you type commands: on Windows the app Windows
# PowerShell (or Terminal), on macOS the app Terminal (it runs the shell zsh), on Linux
# any terminal (it runs the shell bash). Type every command of this section into a
# terminal exactly as printed, one line at a time, and press Enter after each line.
#
# Windows: download Git from https://git-scm.com/download/win and install it with the
# default choices. Download Python from https://www.python.org/downloads/ and run the
# installer; in its first window tick the box "Add python.exe to PATH" before you click
# "Install Now".
#
# macOS: download Python from https://www.python.org/downloads/ and run the installer.
# Then open the app Terminal and run this command, which installs Git and the compiler
# tools:
#
# macOS (zsh):
#     xcode-select --install
#
# Linux (Debian or Ubuntu; other distributions have packages of the same names): run
# these two commands:
#
# Linux (bash):
#     sudo apt update
#     sudo apt install git python3 python3-venv
#
# Then close the terminal and open a NEW one (a terminal opened before the installation
# does not know the new programs), and check the version of Python; it must print 3.12 or
```

```
# a higher number:
#
# Windows (PowerShell):
#     py -3 --version
#
# macOS (zsh) and Linux (bash):
#     python3 --version
#
# If an older Linux prints a lower number (Ubuntu 22.04 has Python 3.10), install Python
# 3.12 with the following three commands, and in Step 3 type python3.12 instead of
# python3 in the command that creates the environment:
#
# Linux (bash), only when the version is too low:
#     sudo add-apt-repository ppa:deadsnakes/ppa
#     sudo apt update
#     sudo apt install python3.12 python3.12-venv
#
# STEP 3. GET THE REPOSITORY AND INSTALL THE PACKAGES (ONCE PER COMPUTER).
#
# The commands below download the repository (a few hundred megabytes; the folder then
# needs up to about 1 GB of disk space) into the folder Dirac_claude inside your home
# folder, create a private Python environment in the folder dirac-book-env inside your
# home folder (a private environment is a folder with its own copy of Python and of the
# packages, so that nothing else on your computer is changed), activate it (from then on
# the commands python and jupyter typed in this terminal are those of the environment,
# and the prompt starts with (dirac-book-env)), and install the packages at the pinned
# versions (this downloads about 90 MB and takes a few minutes; the environment takes
# about 400 MB of disk space). If you have done this step before, for this or for another
# notebook, skip it and go to Step 4; to get the newest version of the repository, run
# git pull in the repository folder after Step 4.
#
# Windows (PowerShell):
#     cd $HOME
#     git clone https://github.com/once-ere/Dirac_claude.git
#     py -3 -m venv "$HOME\dirac-book-env"
#     Set-ExecutionPolicy -ExecutionPolicy RemoteSigned -Scope Process -Force
#     & "$HOME\dirac-book-env\Scripts\Activate.ps1"
#     python -m pip install --upgrade pip
#     python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
#     python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
#     python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
#
# The line with Set-ExecutionPolicy allows PowerShell to run the activation script in
# this one window only; it changes nothing permanently.
#
# macOS (zsh):
#     cd ~
#     git clone https://github.com/once-ere/Dirac_claude.git
#     python3 -m venv ~/dirac-book-env
#     source ~/dirac-book-env/bin/activate
#     python -m pip install --upgrade pip
#     python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
#     python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
#     python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
```

```
#
# Linux (bash):
#     cd ~
#     git clone https://github.com/once-ere/Dirac_claude.git
#     python3 -m venv ~/dirac-book-env
#     source ~/dirac-book-env/bin/activate
#     python -m pip install --upgrade pip
#     python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
#     python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
#     python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
#
# STEP 4. IN EVERY NEW TERMINAL: ACTIVATE THE ENVIRONMENT AND GO INTO THE REPOSITORY
# FOLDER.
#
# Every later step starts in the repository folder with the environment active. Run these
# lines whenever you open a new terminal (they do no harm if the environment is already
# active):
#
# Windows (PowerShell):
#     Set-ExecutionPolicy -ExecutionPolicy RemoteSigned -Scope Process -Force
#     & "$HOME\dirac-book-env\Scripts\Activate.ps1"
#     cd "$HOME\Dirac_claude"
#
# macOS (zsh) and Linux (bash):
#     source ~/dirac-book-env/bin/activate
#     cd ~/Dirac_claude
#
# STEP 5. INSTALL RUST AND BUILD THE RUST PROGRAM (RUST ONCE PER COMPUTER, THE BUILD ONCE
# PER PROGRAM).
#
# Windows: download rustup-init.exe from https://rustup.rs, run it and accept the default
# choices; if it reports that the Visual Studio C++ Build Tools are missing, let it
# install them (or install the workload "Desktop development with C++" from
# https://visualstudio.microsoft.com/visual-cpp-build-tools/ and run rustup-init.exe
# again). macOS and Linux: run the command below and accept the default choice (on Linux
# first run sudo apt install build-essential, which provides the linker that Rust needs).
#
# macOS (zsh) and Linux (bash):
#     curl --proto "=https" --tlsv1.2 -sSf https://sh.rustup.rs | sh
#
# Then close the terminal, open a new one, do Step 4 again, and check the version of
# cargo; it must print 1.91.1 or a newer version:
#
# Windows, macOS and Linux:
#     cargo --version
#
# Build the program with the following command, in the repository folder (the same
# command on all three systems):
#
# Windows, macOS and Linux:
#     cargo build --release --manifest-path Revision/kohn_sham/solver/Cargo.toml
#
# The first build takes about 1 minute; later builds reuse the result and take a few
# seconds. The program is then the file
```

```
# Revision/kohn_sham/solver/target/release/revision_ks_solver (on Windows with the ending
# .exe). The notebook runs the same build command itself before it uses the program (it
# takes a second when the program is up to date), so the notebook also works if you skip
# this build; building here first shows any problem with Rust before the notebook starts.
#
# STEP 6. RUN THE NOTEBOOK IN JUPYTERLAB.
#
# In the repository folder, with the environment active, run these two lines (the first
# one goes into the folder of the notebooks):
#
# Windows, macOS and Linux:
#     cd Revision/textbook/notebooks
#     jupyter lab 15a_canonical_matrix.ipynb
#
# JupyterLab opens in your web browser and shows the notebook (if no browser window
# opens, copy the address that starts with http://localhost:8888/lab from the terminal
# into the address bar of your browser). The name at the top right of the notebook must
# read Python 3 (ipykernel). Choose the menu Run > Run All Cells. While a cell runs, the
# label to its left shows [*]; when it has finished, the label shows a number. The
# notebook has finished when the last code cell shows a number; this takes about 10
# minutes on a typical laptop. Scroll to the end and compare the last printed lines with
# the lines in the step "What the notebook writes and what you must see" below. To keep
# the results, save the notebook (menu File > Save Notebook). To stop JupyterLab, choose
# the menu File > Shut Down, or press Ctrl+C twice in the terminal.
#
# STEP 7. OR RUN THE NOTEBOOK WITHOUT A BROWSER (HEADLESS).
#
# In the repository folder, with the environment active, run:
#
# Windows, macOS and Linux:
#     cd Revision/textbook/notebooks
#     jupyter nbconvert --to notebook --execute --inplace 15a_canonical_matrix.ipynb
#
# This runs every cell from the top to the bottom and saves the results into the notebook
# file. A failed check stops it with an error message that contains AssertionError and
# the name of the check. If the command ends with a line that starts with [NbConvertApp]
# Writing and shows no error, every check passed; open the notebook with jupyter lab
# 15a_canonical_matrix.ipynb (in the same folder, without running the cells again) to
# read the printed lines and see the figures.
#
# STEP 8. WHAT THE NOTEBOOK WRITES AND WHAT YOU MUST SEE.
#
# The notebook writes (or overwrites) these files:
#
# - Revision/textbook/figures/15a.captions.json
# - Revision/textbook/figures/15a_1_levels_history.png
# - Revision/textbook/figures/15a_2_gaps_history.png
# - Revision/textbook/figures/15a_3_delta_scf.png
# - Revision/textbook/figures/15a_4_energy_history.png
# - Revision/textbook/figures/15a_5_densities.png
# - Revision/textbook/figures/15a_6_potentials.png
# - Revision/textbook/figures/15a_7_scf_convergence.png
# - Revision/textbook/figures/15a_8_particle_hole.png
#
```

```
# It changes no other file of the repository except the Rust build folder target next to
# each Cargo.toml it builds (inside it the notebook keeps the raw output of its program
# runs in Revision/kohn_sham/solver/target/textbook_15a, which git ignores); running it
# headless or saving it in JupyterLab also rewrites the notebook file itself. It does not
# use the internet while it runs. The files it writes are the same files that are stored
# in the repository (on another computer a figure may differ in a few bytes, which is
# harmless). To get the stored versions back, run this command in the repository folder
# (it also undoes every change you made yourself in the folder Revision/textbook):
#
# Windows, macOS and Linux:
#     git checkout -- Revision/textbook
#
# Every check of the notebook prints a line that starts with PASS. At the end of the
# notebook (the output of its last code cell) you must see exactly these lines:
#
#     PASS every figure file of this notebook exists
#     ALL 25 CHECKS PASSED (notebook 15a)
#
# and the notebook must show 8 figures below the cells that draw them.
#
# STEP 9. IF SOMETHING GOES WRONG.
#
# - "ModuleNotFoundError: No module named ..." in the notebook: JupyterLab was started
#   without the environment. Stop it (menu File > Shut Down), do Step 4, and start it
#   again. If the error remains, another Python installation has registered its own
#   kernel called python3; with the environment active, run the following command and
#   start JupyterLab again:
#     python -m ipykernel install --user --name python3
# - "FileNotFoundError: The repository folder was not found": the notebook was opened
#   from a copy outside the repository. Open the file
#   Revision/textbook/notebooks/15a_canonical_matrix.ipynb inside the folder
#   Dirac_claude.
# - "fatal: destination path 'Dirac_claude' already exists" in Step 3: the repository was
#   downloaded before; skip the line with git clone.
# - Windows: "running scripts is disabled on this system": run the line with
#   Set-ExecutionPolicy and then the activation line again. "py is not recognized": use
#   python instead of py -3; "python is not recognized": install Python again and tick
#   "Add python.exe to PATH".
# - Linux: "ensurepip is not available" when the environment is created: run sudo apt
#   install python3-venv and repeat Step 3.
# - "jupyter is not recognized" or "command not found: jupyter": the environment is not
#   active; do Step 4. If the environment is active and the message stays, the programs
#   jupyter-lab and jupyter-nbconvert are not in the folders where the terminal looks for
#   programs (python -m jupyter does not help then: it has to find the same programs).
#   Start them through Python itself, in the folder of the notebook: the first command
#   below does what jupyter lab does, the second what the headless command does:
#     python -m jupyterlab 15a_canonical_matrix.ipynb
#     python -m nbconvert --execute --inplace 15a_canonical_matrix.ipynb
# - Windows: the headless run prints a RuntimeWarning that mentions the "Proactor event
#   loop" and zmq: this is a message of the package pyzmq, not an error; the run
#   continues normally.
# - A red box with "Matplotlib is building the font cache; this may take a moment." in
#   the first run after the installation: this is a message, not an error; the run
#   continues and the message does not come again.
```

```
# - An AssertionError names a check that failed: choose the menu Kernel > Restart Kernel
#   and Run All Cells; if it fails again, install the packages again with the pip
#   commands of Step 3, because a different package version can change the last digits of
#   a result.
# - "cargo is not recognized" or "command not found: cargo" or "cargo was not found":
#   open a new terminal after installing Rust, do Step 4 again, and start JupyterLab from
#   this terminal.
# - "linker link.exe not found" (Windows) or "linker cc not found" (Linux): install the
#   C++ Build Tools (Windows) or build-essential (Linux) as described in Step 5 and build
#   again.
# - The cell that runs the canonical matrix shows the label with the star for several
#   minutes: this is normal. The solver computes 210 states and uses up to 22 processor
#   cores; on the computer that built the notebook (22 cores) the whole notebook takes
#   two to four minutes, and on a computer with 4 cores it can need up to about 10
#   minutes. Wait until the label shows a number.
# - An AssertionError names one of the comparisons with the record: the notebook prints
#   the largest difference just above the error. Differences far below the tolerance are
#   rounding effects of another computer; a larger difference means that the solver or
#   its input files were changed. Get the stored versions back and run the notebook
#   again.
#     git checkout -- Revision/kohn_sham
# - You want the disk space of the solver output back: the folder
#   Revision/kohn_sham/solver/target/textbook_15a holds only the raw output of the last
#   run (ignored by git); delete it at any time, the notebook writes it again.
#
# ------------------------------------------------------------------------------------

## 3. The words used in this notebook

- **Kohn-Sham state**: an approximate state of many identical fermions, built from
  one-particle wave functions (*orbitals*) that each solve a one-particle equation
  in a common *effective potential*; the potential depends on the densities of the
  occupied orbitals, so the equations must be solved *self-consistently*.
- **Level**: an allowed energy $\varepsilon$ of the one-particle equation. A level is
  **occupied** if particles sit in it ($f = 1$) and **empty** if not ($f = 0$).
- **Degeneracy** $g$: the number of different orbitals that share one level.
- **HOMO, LUMO, Kohn-Sham gap**: the highest occupied and the lowest unoccupied
  level, and their difference $\Delta_{KS} = \varepsilon_{LUMO} - \varepsilon_{HOMO}$.
- **Delta-SCF**: the energy of the first excited state minus the energy of the
  ground state, both computed self-consistently (SCF = self-consistent field).
- **Slice** $a_{4,0}$: one instant of the history, the value of the metric function
  $a_4$ at that instant. The **history** is $a_4 = A H x_4$ with $A = 1$.
- **Canonical matrix**: the fixed list of states the solver computes: particle
  numbers $N = 8, 136, 688$; couplings $\lambda = 0, \pm\lambda_1, \pm\lambda_2$;
  slices $a_{4,0} = 0, 0.5, 1, 1.5, 2$; and temperatures $T = 0.01, 0.02, 0.05$
  (in units of the mass $m$) for $\lambda = 0, \pm\lambda_1$.
- **Proper density**: a number of particles (or an energy) per unit of proper
  7-volume. **Coordinate density**: the same per unit of the coordinate $y$ (it
  contains the volume factor $e^{6Hy}$).
- **Brane** and **tip**: the two ends $y = 0$ and $y = -L = -3$ of the hidden
  coordinate.
- **Shell** $n_2$: the 3-space momenta form a lattice $\vec k = \Delta k\,\vec n$
  with $\vec n$ a vector of three whole numbers; a shell collects the $r_3(n_2)$
  vectors with the same $n_2 = |\vec n|^2$, so $|\vec k| = \Delta k \sqrt{n_2}$.
- **Residual**: in the self-consistent loop, the largest change of the potential
  from one iteration to the next; the loop stops when it is below $10^{-11}$.
- **Anderson mixing**: a rule that builds the next potential from several earlier
  ones; it converges much faster than simple mixing.
- **Manifest, sha256**: the solver writes a list (the manifest) of all its files
  with a 64-digit *fingerprint* (sha256) of each; two files with the same
  fingerprint are identical byte for byte.
- **Tolerance**: the largest difference that a comparison accepts; the tolerances
  used here were fixed in advance in the Revision record.
```

Text cell:

```
## 4. The physical and mathematical situation

**The field and the metric.** The author's metric has eight coordinates $x_0$ to
$x_7$. The directions $x_1, x_2, x_3$ are ordinary 3-space, with the scale factor
$e^{a_4} \sin^{1/6} z$; $x_4$ is the time; $x_5, x_6, x_7$ are the three **extra
times**, with the scale factor $e^{-a_4} \sin^{1/6} z$, so they **deflate
exponentially** while $a_4$ grows; $x_0$ is the hidden space direction, with
$z = 6 H x_0$ between $0$ and $\pi/2$. The Kohn-Sham model uses the hidden
coordinate $y = \ln(\sin z)/(6H)$, which runs from the tip $y = -L$ (the model cuts
the space there, with $L = 3$) to the brane $y = 0$ (the end $z = \pi/2$ of the
patch).

**The equation the solver solves.** For one 3-momentum $k = |\vec k|$ and one of
two block types $j = \pm 1$ the 16-component field reduces exactly to a pair of
real functions $a(y), b(y)$ (an orbital) with

$$a' = M a - (\kappa k + j(\varepsilon - v))\, b, \qquad
b' = (j(\varepsilon - v) - \kappa k)\, a - M b,$$

where the prime is $d/dy$, $\kappa = e^{-Hy - a_{4,0}}$, $M(y) = m + \tfrac{15}{16}
\lambda S(y)$ is the effective mass and $v(y) = -\tfrac{1}{16} \lambda n(y)$ the
effective potential, with $n$ and $S$ the proper number and scalar densities of
the occupied orbitals. The slice $a_{4,0}$ enters only through $\kappa$: along the
history every 3-momentum is **redshifted**, $k \to k e^{-a_{4,0}}$.

**Boundary conditions.** At the tip $b(-L) = 0$ (a regular tip, a choice). At the
brane the Z2 mirror, which is ASSUMED: $b(0) = 0$ (even parity) or $a(0) = 0$ (odd
parity).

**Status of the history.** The history $a_4 = A H x_4$ with $A = 1$ is a PRESCRIBED
BACKGROUND: it is not solved for, and the Kohn-Sham states are not an admissible
source of the equations for $a_4$ (the Revision record
Revision/field_equations_a4/reports/ks-source-conditions.json). The states are
**instantaneous** (adiabatic) states at each slice.

**Parameters** (units $H = m = 1$): $L = 3$, $\Delta k = 0.25$, $N = 8$ (the eight
zero modes at $k = 0$), $N = 136$ and $N = 688$ (closed shells of the brane band),
and per $N$ the couplings $\lambda_1, \lambda_2$ that make the first-order
potential $0.1\,m$ and $0.3\,m$ where it is largest, over every point and every
slice, so that it stays below these values along the whole history
(Revision/kohn_sham/results/parameters.json).
Particles fill the positive branch and the zero modes, a CONVENTION whose
justification is OPEN. $N$ counts the particles of the doubled system (universe and
Z2 image); one patch holds $N/2$.

All numbers of this notebook are COMPUTED by the solver; the notebook checks that
they agree with the committed record.
```

Text cell:

```
## 5. Building the solver
```

The next cell imports the packages of this notebook and builds the Rust program ‘revision_ks_solver‘ with cargo (the helper ‘rust_program‘ of the set-up cell runs ‘cargo build --release‘ for the crate; the first build takes about a minute, later builds a second). ‘PALETTE‘ holds the colours of the figures: eight distinct hues in a fixed order, and five shades of blue for the five slices of the history (light for the earliest, dark for the latest).

In [2]:

```
import csv  # reads the tables (CSV files) that the solver writes
import math  # exp, sqrt and pi for single numbers

import numpy as np  # arrays of numbers

SOLVER_MANIFEST = "Revision/kohn_sham/solver/Cargo.toml"  # the crate of the solver
program = rust_program(SOLVER_MANIFEST, "revision_ks_solver")  # build it, get its path

PALETTE = ["#2a78d6", "#eb6834", "#1baf7a", "#eda100", "#e87ba4", "#008300",
           "#4a3aa7", "#e34948"]  # blue, orange, aqua, yellow, magenta, green, ...
SLICE_SHADES = ["#86b6ef", "#5598e7", "#2a78d6", "#1c5cab", "#104281"]  # light->dark
SLICES = [0.0, 0.5, 1.0, 1.5, 2.0]  # the five slices a4,0 of the history
say("Packages imported; colours defined.")
```

Out [2]:

```
Rust program revision_ks_solver is built and ready.
Packages imported; colours defined.
```

Text cell:

```
## 6. Running the canonical matrix

The next cell runs ‘revision_ks_solver all‘. The option ‘--root‘ tells the program where the repository is (it reads the theory file ‘Revision/kohn_sham/ks-theory.json‘, the gamma matrices ‘Revision/algebra/gammas.json‘ and one fixture file from there); ‘--out‘ and ‘--report‘ name the folder of the results and the file of the check report. Both go into the folder ‘textbook_15a‘ inside the Rust build folder ‘target‘, so the committed record is never touched. A folder left over from an interrupted run is removed first (the solver refuses to write into a folder without its manifest). The solver prints one line per check on its error stream and ‘SUCCESS‘ as its last line on its output stream; the cell counts those lines. This cell takes two to three minutes on a computer with many cores (up to about ten minutes on a laptop).
```

In [3]:

```
RUN_FOLDER = REPO / "Revision/kohn_sham/solver/target/textbook_15a"  # git ignores it
NEW_RESULTS = RUN_FOLDER / "results"  # the new canonical matrix
```

```
NEW_REPORT = RUN_FOLDER / "ks-rust-solver.json"  # the new check report
RUN_FOLDER.mkdir(parents=True, exist_ok=True)
if NEW_RESULTS.exists() and not (NEW_RESULTS / "manifest.json").exists():
    shutil.rmtree(NEW_RESULTS)  # remains of an interrupted run
completed = subprocess.run(
    [str(program), "all", "--root", str(REPO), "--out", str(NEW_RESULTS),
     "--report", str(NEW_REPORT)],
    capture_output=True, text=True, encoding="utf-8", errors="replace")
stdout_lines = completed.stdout.strip().split("\n")  # what it printed on stdout
stderr_lines = completed.stderr.split("\n")  # its check lines and timings
pass_count = sum(1 for line in stderr_lines if line.startswith("PASS - "))
fail_count = sum(1 for line in stderr_lines if line.startswith("FAIL - "))
say(f"exit code {completed.returncode}, last line {stdout_lines[-1]!r}, "
    f"{pass_count} PASS lines, {fail_count} FAIL lines")
check(completed.returncode == 0 and stdout_lines[-1] == "SUCCESS" and fail_count == 0,
      "the solver ran the whole canonical matrix and reported SUCCESS")
```

Out [3]:

```
exit code 0, last line 'SUCCESS', 42 PASS lines, 0 FAIL lines
PASS the solver ran the whole canonical matrix and reported SUCCESS
```

Text cell:

```
## 7. The solver's own check report

The solver writes its checks into a JSON report. The next cell reads the new report
and the committed one, prints how many checks of each group there are (the group
is the first word of the check name, for example `ground` or `thermo`), and checks
that every check passes, that the new report has the same summary (number of
checks, of PASS and of FAIL) as the committed report, and that it lists the same
checks in the same order. Whether the two reports are identical byte for byte is
printed as a RESULT line: on the computer that built this book they are; on another
computer the last digits of some reported deviations may differ.
```

In [4]:

```
RECORD_REPORT = "Revision/kohn_sham/reports/ks-rust-solver.json"
new_report = json.loads(NEW_REPORT.read_text(encoding="utf-8"))
old_report = json.loads(repository_file(RECORD_REPORT).read_text(encoding="utf-8"))
groups = {}  # first word of a check name -> [number of checks, number of PASS]
for item in new_report["checks"]:
    group = item["name"].split("_")[0]
    groups.setdefault(group, [0, 0])
    groups[group][0] += 1
    groups[group][1] += item["verdict"] == "PASS"  # True counts as 1
for group, (count, passed) in groups.items():
    say(f"  {group:10} {count:2d} checks, {passed:2d} PASS")
new_names = [item["name"] for item in new_report["checks"]]
old_names = [item["name"] for item in old_report["checks"]]
summary = new_report["summary"]  # {"checks": ..., "pass": ..., "fail": ...}
```

```
report("checks in the new report / PASS / FAIL",
       f"{summary['checks']} / {summary['pass']} / {summary['fail']}")
check(summary == old_report["summary"] and summary["fail"] == 0
      and summary["pass"] == summary["checks"] == len(new_names),
      f"the new report holds the {summary['checks']} checks of the record, all PASS",
      record=f"{RECORD_REPORT}, summary")
check(new_names == old_names, "the new report has the same checks as the record")
report("new report byte-identical to the record",
       NEW_REPORT.read_bytes() == repository_file(RECORD_REPORT).read_bytes())
```

Out [4]:

```
  theory      1 checks,  1 PASS
  gamma       1 checks,  1 PASS
  block       1 checks,  1 PASS
  free        7 checks,  7 PASS
  adiabatic   2 checks,  2 PASS
  thermo     11 checks, 11 PASS
  t3          1 checks,  1 PASS

  excited     2 checks,  2 PASS
  exx         2 checks,  2 PASS
  ground      7 checks,  7 PASS
  rescaling   2 checks,  2 PASS
RESULT checks in the new report / PASS / FAIL = 42 / 42 / 0
PASS the new report holds the 42 checks of the record, all PASS
     reproduces Revision/kohn_sham/reports/ks-rust-solver.json, summary
PASS the new report has the same checks as the record
RESULT new report byte-identical to the record = True
```

Text cell:

```
## 8. Comparing every result file with the record

The solver's manifest lists every result file with its sha256 fingerprint. The next
cell checks that the new run wrote exactly the same set of files as the record and
counts how many have the same fingerprint (byte-identical files).
```

In [5]:

```
RECORD_RESULTS = "Revision/kohn_sham/results"

def manifest_of(folder):
    """{file path: sha256} of the manifest.json in folder."""
    data = json.loads((folder / "manifest.json").read_text(encoding="utf-8"))
    return {entry["path"]: entry["sha256"] for entry in data["files"]}

old_manifest = manifest_of(repository_file(RECORD_RESULTS))
new_manifest = manifest_of(NEW_RESULTS)
```

```
check(sorted(old_manifest) == sorted(new_manifest),
      f"the new run wrote the same {len(old_manifest)} result files as the record",
      record=f"{RECORD_RESULTS}/manifest.json")
same = sum(1 for path in old_manifest if new_manifest[path] == old_manifest[path])
report("result files byte-identical to the record", f"{same} of {len(old_manifest)}")
```

Out [5]:

```
PASS the new run wrote the same 243 result files as the record
     reproduces Revision/kohn_sham/results/manifest.json
RESULT result files byte-identical to the record = 243 of 243
```

Text cell:

```
Byte identity can fail on another computer only through the last digit of a number
(operating systems compute $e^x$ and $\ln x$ with slightly different rounding). The
meaningful comparison is therefore numerical. The next cell reads four tables of the
new run and of the record and computes the largest difference of their key columns:
the energies $E_{KS}$ of the 75 ground states (relative to $\max(|E|, 1)$), their
HOMO, LUMO and gap (absolute, in units of $m$), the Delta-SCF energies, the
chemical potential $\mu$, energy, entropy and free energy of the 135 thermal states,
and the adiabaticity measure $Q_{max}$. The tolerances are those fixed in advance in
Revision/kohn_sham/reports/ks-rust-determinism.json: $10^{-8}$ for eigenvalues,
energies and thermodynamics, $10^{-6}$ for derived quantities.
```

In [6]:

```

## 10. The Kohn-Sham levels along the history

The next cell reads, for $N = 136$ and $\lambda = 0$, the level tables of the five
slices. Each level has a **key**: its shell $n_2$, block type $j$, parity and
Pruefer label $l$ (the label numbers the levels of one sector in the order of their
energies, and a level keeps its label when the potentials change continuously, so
the label identifies the same level at every slice). The figure follows each key across
the slices: the **brane band** (the lowest even level of $j = +1$ in each shell
$n_2 \ge 1$) comes down as the history proceeds, while the levels at $k = 0$ do not
move at all, because $a_{4,0}$ enters only through $\kappa k$. The dashed line is
the small-$k$ law $\varepsilon \approx c\, k\, e^{-a_{4,0}}$ for the first shell
($k = 0.25$), with the slope $c = 1.9051482536$ of Revision/kohn_sham/ks-theory.json.

The checks: every $k = 0$ level is the same at all five slices (to $10^{-12}$), and
every brane-band level present at all slices decreases strictly along the history.
```

## 11. The gaps along the history

The next cell draws the Kohn-Sham gap of $N = 8$, $136$ and $688$ (without
interaction) against the slice on a logarithmic vertical axis, together with dashed
lines proportional to $e^{-a_{4,0}}$ through the first point of each curve. Every gap
shrinks along the history, somewhat more slowly than $e^{-a_{4,0}}$: the gap is the
distance between two brane-band levels (for $N = 688$ at $a_{4,0} = 0$ between a band
level and the bulk level at $k = 0$), and the band levels approach the straight line
$c\,k\,e^{-a_{4,0}}$ only when the redshifted momenta $k e^{-a_{4,0}}$ are small.
Without interaction the levels do not change when one particle is
moved, so the Delta-SCF energy must equal the gap exactly; the solver recorded this
as its check ‘excited_delta_scf_free_equals_gap‘.
```

## 12. The total energy along the history

The next cell draws $E_{KS}$ of $N = 136$ and $688$ without interaction (left) and
the change of $E_{KS}$ caused by the interaction, $E_{KS}(\lambda) - E_{KS}(0)$, for
$N = 136$ (right). The energy of the gas falls along the history because the brane
band redshifts. A repulsive coupling ($\lambda > 0$) raises the energy and an
attractive one lowers it, for $N = 136$ and $N = 688$; the check confirms this order
at every slice. (For $N = 8$ the order is reversed: the eight zero modes have no
scalar density $S$, so to first order in $\lambda$ the only interaction energy is
the exchange term $-\tfrac{1}{32}\lambda n^2$, which is negative for $\lambda > 0$.)
```

## 13. Where the particles are: the densities

The solver writes for every ground state the **profiles**: the densities and the
energy-momentum tensor at the 151 points $y = -3, -2.98, \dots, 0$. The next cell
reads the proper number density $n(y)$ of $N = 136$ without interaction at the
slices $0$, $1$ and $2$ and draws it (left, logarithmic) together with the number of
particles per unit of $y$, $2\,\mathrm{Vol}_7\, e^{6Hy} n(y)$ (right), where
```

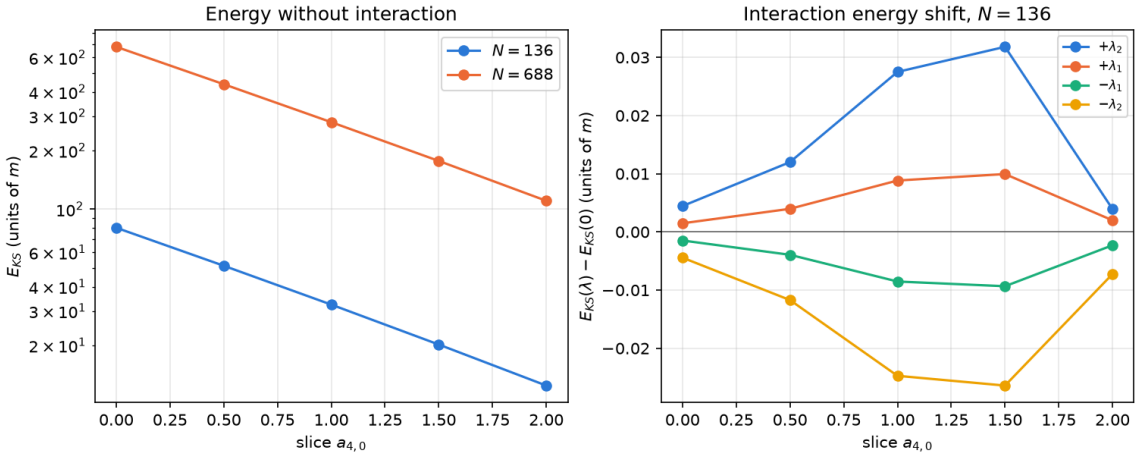

Figure 414: Left: the Kohn-Sham energy E_{KS} (vertical axis, logarithmic, units of m) of $N = 136$ and $N = 688$ without interaction at the five slices; it falls along the history as the brane band redshifts. Right: the energy shift caused by the couplings $\pm\lambda_1$ and $\pm\lambda_2$ for $N = 136$ (vertical axis, units of m): repulsion raises and attraction lowers the energy, by at most $0.032\,m$ out of 12 to $80\,m$. (Notebook 15a, figure 4.)

```
$\mathrm{Vol}_7 = (2\pi/\Delta k)^3$ is the proper 7-volume of the box per unit of
$e^{6Hy}$. The proper density is largest at the tip (the proper volume
$e^{6Hy}$ is tiny there), but the particles themselves sit near the brane; along the
history they spread toward the tip.

The integral of the right-hand curve over $y$ must be $N = 136$. It is computed with
**Simpson's rule** on the 151 points (step $h = 0.02$): $\int f\,dy \approx
\tfrac{h}{3}(f_0 + 4 f_1 + 2 f_2 + 4 f_3 + \dots + 4 f_{149} + f_{150})$.
```

## 14. The self-consistent potentials

With interaction the effective mass $M(y) = m + \tfrac{15}{16}\lambda S(y)$ and the
potential $v(y) = -\tfrac{1}{16}\lambda n(y)$ differ from $m$ and $0$. The next cell
draws $M - m$ and $v$ for $N = 136$ with the repulsive coupling $+\lambda_2$ at the
five slices. Both are largest in the tip region and become much larger along the
history (the largest $|v|$ grows at every slice; the largest $|M - m|$ grows up to
$a_{4,0} = 1.5$ and is a little smaller at $a_{4,0} = 2$), because the redshifted
brane-band orbitals spread toward the tip, where the proper densities are large.
This is why the couplings were calibrated over the whole history (so that the
first-order potential stays below $0.3\,m$ at every slice).
The check compares, for each slice, the largest $|M - m|$ on the 151 profile points
with the value `max_abs_Meff_minus_m` that the solver recorded on its fine grid of
1801 points (every profile point is also a point of the fine grid): the profile
value cannot be larger, and since the maximum lies between two profile points it
is smaller by a little, at most 0.2 percent.
```

## 15. How fast the self-consistent loop converges

The file ‘ground/runs.json‘ records for every ground state the residual of each
iteration of the self-consistent loop. The next cell draws it for the strongest
couplings $\pm\lambda_2$ at the last slice $a_{4,0} = 2$ (the hardest cases), with
the tolerance $10^{-11}$ as a dotted line, and checks that all 75 ground states
converged directly (path ‘direct‘: no fallback was needed) with a final residual at
or below the tolerance (zero for $\lambda = 0$, where one iteration suffices).
```

In [14]:

```
runs = json.loads((NEW_RESULTS / "ground/runs.json").read_text(encoding="utf-8"))

## 16. The excitations of the gas along the history

For every ground state the solver also lists its lowest **particle-hole
excitations** (up to 24, in the files ‘excited/particle-hole/<state>.csv‘): one
particle is taken out of an occupied level (the *hole*) and put into an empty level
```

(the *particle*); the excitation energy is $\Delta\varepsilon =
\varepsilon_{particle} - \varepsilon_{hole}$, and the *multiplicity* is the number
of ways to do it, $g_{hole} \times g_{particle}$. Each excitation is named by its
two levels, written ‘n2:j:parity:label‘. The next cell draws the excitations of
$N = 136$ without interaction at the five slices and makes three checks over all
75 states: (1) the lowest excitation is the Kohn-Sham gap; (2) every excitation
listed at all five slices of a series gets cheaper from slice to slice; (3) none of
the listed excitations stays inside one *sector* (the same shell n_2, block type
j and parity). The third point matters for the history: the exact evolution
along $a_4 = AHx_4$ keeps the momentum, the block type and the parity of every
orbital, so the history alone cannot create any of these excitations. It can only
cause jumps inside a sector; the cell prints the energy of the jump with the
largest adiabaticity number Q of each state (column ‘Q_max_delta_eps‘ of
‘adiabatic/adiabaticity.csv‘), which is much larger.

## 18. What this notebook showed

- The Rust solver, built on this computer, reproduces the whole canonical matrix of
  the Revision record: the same files, every one of its own checks PASS, and every
  key number within the tolerances fixed in advance (COMPUTED).
- Along the deflating history the brane band redshifts like $k e^{-a_{4,0}}$, the
  levels at $k = 0$ stay where they are, the gaps close at nearly the rate
  $e^{-a_{4,0}}$, and the energy of the gas falls.
- Without interaction Delta-SCF equals the gap exactly; with interaction the orbital
  relaxation stays below $10^{-3}\,m$. The lowest particle-hole excitation is the
  gap, every listed excitation gets cheaper along the history, and none of them
  stays inside one sector, so the history alone cannot create them.
- The particles sit near the brane, the proper densities and the self-consistent
  potentials are largest at the tip, and the self-consistent loop converges in at
  most 17 iterations.
- These are instantaneous states on a PRESCRIBED background; the brane is ASSUMED;
  the filling is a CONVENTION; whether the gas really follows the instantaneous
  states along the history is the question of adiabaticity, which the solver
  measures with the number $Q_{max}$ compared above.
```

15.14 Line-by-line walk-through of Notebook 15a

The notebook has 16 code cells, In [1] to In [16]. As in Section 15.9, docstrings are left out of the quotations, and long caption strings in calls of `save_figure` are shortened: the quotation shows the first line of the call and the first line of the caption, and then a line `...)` that stands for the rest of the caption and the closing parenthesis; the complete cells are printed in Section 15.13.

In [1], the set-up cell. It is the set-up cell of Notebook 15e (explained line by line in Section 15.9), with three differences: the comment lines at the top hold the run instructions of this notebook (Section 15.12), the line `NOTEBOOK_ID = "15a"` names it, and, because this notebook runs a Rust program, it has two more imports and one more function:

```
import shutil  # finds the program cargo
import subprocess  # runs cargo and the Rust programs
```

`shutil` is a module of Python for files and programs; its function `shutil.which` finds a program on the computer, and `shutil.rmtree` deletes a folder with everything in it. `subprocess` runs another program from Python and collects what it prints.

```
def rust_program(manifest, binary):
    if shutil.which("cargo") is None:
        raise FileNotFoundError(
            "cargo was not found: install Rust from https://rustup.rs, open a new "
            "terminal, activate the environment and start JupyterLab again")
    crate = (REPO / manifest).parent  # the folder that holds Cargo.toml
```

`rust_program` builds a Rust program and returns where it is. `manifest` is the repository path of the crate's file `Cargo.toml` (a **crate** is a Rust project; `Cargo.toml` describes it), and `binary` is the name of the program. If `shutil.which("cargo")` finds no program cargo, the function stops with a message that says how to install Rust. `crate` is the folder that holds `Cargo.toml` (`.parent` is the folder above a path).

```
    completed = subprocess.run(
        ["cargo", "build", "--release", "--manifest-path", str(REPO / manifest),
         "--target-dir", str(crate / "target")],
        capture_output=True, text=True, encoding="utf-8", errors="replace")
    if completed.returncode != 0:  # show the end of cargo's error message
        print(completed.stderr[-3000:])
        raise RuntimeError(f"cargo build failed for {manifest}")
```

`subprocess.run([...])` runs the command given as a list of words: cargo builds the crate in release mode (the fast, optimised translation) into the crate's own folder `target`. `capture_output=True` collects what cargo prints instead of showing it, `text=True` with `encoding="utf-8"` turns it into text, and `errors="replace"` replaces any byte that is not valid text. When cargo has nothing to do (the program is up to date) this takes about a second; the first build takes a minute or two. A program reports success with the **return code** 0; any other code means failure, and then the last 3000 characters of cargo's error stream (`stderr[-3000:]`) are printed and the notebook stops.

```
    for file_name in (binary, binary + ".exe"):  # Linux and macOS; Windows
        path = crate / "target" / "release" / file_name
        if path.is_file():
            say(f"Rust program {binary} is built and ready.")
            return path
    raise FileNotFoundError(f"cargo built {manifest} but {binary} is missing")
```

The program lies in `target/release`; on Windows its file name ends with `.exe`, on Linux and macOS it has no ending, so both names are tried. The function prints that the program is ready and returns its path.

In [2], building the solver.

```
import csv  # reads the tables (CSV files) that the solver writes
import math  # exp, sqrt and pi for single numbers

import numpy as np  # arrays of numbers

SOLVER_MANIFEST = "Revision/kohn_sham/solver/Cargo.toml"  # the crate of the solver
program = rust_program(SOLVER_MANIFEST, "revision_ks_solver")  # build it, get its path
```

After the imports (Section 15.9, In [2]) the cell builds the solver and keeps the path of the program in `program`.

```
PALETTE = ["#2a78d6", "#eb6834", "#1baf7a", "#eda100", "#e87ba4", "#008300",
           "#4a3aa7", "#e34948"]  # blue, orange, aqua, yellow, magenta, green, ...
SLICE_SHADES = ["#86b6ef", "#5598e7", "#2a78d6", "#1c5cab", "#104281"]  # light->dark
SLICES = [0.0, 0.5, 1.0, 1.5, 2.0]  # the five slices a4,0 of the history
say("Packages imported; colours defined.")
```

`PALETTE` holds eight distinct colours, `SLICE_SHADES` five shades of blue for the five slices (light for the earliest, dark for the latest), and `SLICES` the slices $a_{4,0}$. Out [2] prints that the program is built and the line of the last statement.

In [3], running the canonical matrix.

```
RUN_FOLDER = REPO / "Revision/kohn_sham/solver/target/textbook_15a"  # git ignores it
NEW_RESULTS = RUN_FOLDER / "results"  # the new canonical matrix
NEW_REPORT = RUN_FOLDER / "ks-rust-solver.json"  # the new check report
RUN_FOLDER.mkdir(parents=True, exist_ok=True)
if NEW_RESULTS.exists() and not (NEW_RESULTS / "manifest.json").exists():
    shutil.rmtree(NEW_RESULTS)  # remains of an interrupted run
```

The new run is written into the folder `textbook_15a` inside the solver's build folder `target`, which git ignores; the committed record is never touched. The folder is created if necessary. If a results folder exists without its `manifest.json`, an earlier run was interrupted, and the solver would refuse to write into it; `shutil.rmtree` removes it.

```
completed = subprocess.run(
    [str(program), "all", "--root", str(REPO), "--out", str(NEW_RESULTS),
     "--report", str(NEW_REPORT)],
    capture_output=True, text=True, encoding="utf-8", errors="replace")
stdout_lines = completed.stdout.strip().split("\n")  # what it printed on stdout
stderr_lines = completed.stderr.split("\n")  # its check lines and timings
```

The solver runs the command `all`. Its option root (written, like every option, with two hyphens in front) tells it where the repository is (it reads the theory file, the gamma matrices and the fixture of 40-digit chemical potentials from there), and the options out and report name the folder of the results and the file of the check report. This is the longest step of the notebook. The printed text is split into lines: `.strip()` removes the blank space at the ends, `.split("\n")` cuts at the line ends.

```
pass_count = sum(1 for line in stderr_lines if line.startswith("PASS - "))
fail_count = sum(1 for line in stderr_lines if line.startswith("FAIL - "))
say(f"exit code {completed.returncode}, last line {stdout_lines[-1]!r}, "
    f"{pass_count} PASS lines, {fail_count} FAIL lines")
check(completed.returncode == 0 and stdout_lines[-1] == "SUCCESS" and fail_count == 0,
      "the solver ran the whole canonical matrix and reported SUCCESS")
```

`sum(1 for line in ... if ...)` counts the lines that start with PASS - and with FAIL -. The format `!r` prints the last output line with quotes. Out [3] prints exit code 0, the last line SUCCESS, 42 PASS lines and 0 FAIL lines, and the check passes.

In [4], the solver's check report.

```
RECORD_REPORT = "Revision/kohn_sham/reports/ks-rust-solver.json"
new_report = json.loads(NEW_REPORT.read_text(encoding="utf-8"))
old_report = json.loads(repository_file(RECORD_REPORT).read_text(encoding="utf-8"))
groups = {}  # first word of a check name -> [number of checks, number of PASS]
for item in new_report["checks"]:
    group = item["name"].split("_")[0]
    groups.setdefault(group, [0, 0])
    groups[group][0] += 1
    groups[group][1] += item["verdict"] == "PASS"  # True counts as 1
for group, (count, passed) in groups.items():
    say(f"  {group:10} {count:2d} checks, {passed:2d} PASS")
```

The new report and the committed one are read. Each check has a name, a verdict and a detail; the first word of the name (the text before the first underscore) is its group. For each group the cell counts the checks and the passed ones (a comparison gives `True` or `False`, which count as 1 and 0 when added). Out [4] lists the twelve groups, for example free with 7 checks and thermo with 11, all passed.

```
new_names = [item["name"] for item in new_report["checks"]]
old_names = [item["name"] for item in old_report["checks"]]
summary = new_report["summary"]  # {"checks": ..., "pass": ..., "fail": ...}
report("checks in the new report / PASS / FAIL",
       f"{summary['checks']} / {summary['pass']} / {summary['fail']}")
check(summary == old_report["summary"] and summary["fail"] == 0
      and summary["pass"] == summary["checks"] == len(new_names),
      f"the new report holds the {summary['checks']} checks of the record, all PASS",
      record=f"{RECORD_REPORT}, summary")
check(new_names == old_names, "the new report has the same checks as the record")
report("new report byte-identical to the record",
       NEW_REPORT.read_bytes() == repository_file(RECORD_REPORT).read_bytes())
```

The lists of check names of the two reports and the summary of the new one are formed. The first check requires the same summary as the record, no failure, and as many passes as checks; the number 42 is not typed into the notebook but read from the report. The second requires the same check names in the same order. The last line compares the two report files byte for byte (`read_bytes` reads a file as raw bytes); Out [4] prints True: on the computer that built the book the new

report is identical to the record. On another computer the last digits of some reported deviations may differ, which is why this is a RESULT and not a check.

In [5], every result file.

```
RECORD_RESULTS = "Revision/kohn_sham/results"

def manifest_of(folder):
    data = json.loads((folder / "manifest.json").read_text(encoding="utf-8"))
    return {entry["path"]: entry["sha256"] for entry in data["files"]}

old_manifest = manifest_of(repository_file(RECORD_RESULTS))
new_manifest = manifest_of(NEW_RESULTS)
check(sorted(old_manifest) == sorted(new_manifest),
      f"the new run wrote the same {len(old_manifest)} result files as the record",
      record=f"{RECORD_RESULTS}/manifest.json")
same = sum(1 for path in old_manifest if new_manifest[path] == old_manifest[path])
report("result files byte-identical to the record", f"{same} of {len(old_manifest)}")
```

`manifest_of` reads a manifest and returns a dictionary from each file path to its sha256 fingerprint. `sorted(old_manifest)` is the sorted list of the paths; the check requires the same set of files. `same` counts the files whose fingerprints agree. Out [5]: the same 243 result files, all 243 byte-identical to the record.

In [6], the numerical comparison.

```
def read_table(folder, name):
    with open(folder / name, newline="", encoding="utf-8") as handle:
        return {row["id"]: row for row in csv.DictReader(handle)}
```

`read_table` reads a CSV table of the results and files its rows under the state name in the column `id`.

```
def worst(table, columns, relative):
    new = read_table(NEW_RESULTS, table)
    old = read_table(repository_file(RECORD_RESULTS), table)
    assert sorted(new) == sorted(old), f"{table}: the state lists differ"
    largest = 0.0
    for key in old:
        for column in columns:
            a, b = float(new[key][column]), float(old[key][column])
            scale = max(abs(b), 1.0) if relative else 1.0
            largest = max(largest, abs(a - b) / scale)
    return largest
```

`worst` returns the largest difference between the new run and the record in the given columns of a table, over all states. The `assert` statement stops with the given message if the two tables do not list the same states (a safety net inside a helper, not one of the notebook's checks). For a relative comparison each difference is divided by the larger of $|b|$ and 1, so that numbers near zero are compared absolutely.

```
COMPARISONS = [  # (table, columns, relative?, tolerance, what)
    ("ground/summary.csv", ["E_KS"], True, 1e-8, "ground-state energies"),
    ("ground/summary.csv", ["HOMO", "LUMO", "KS_gap"], False, 1e-8,
     "HOMO, LUMO and gaps"),
    ("excited/summary.csv", ["delta_SCF"], False, 1e-8, "Delta-SCF energies"),
    ("thermo/thermodynamics.csv", ["mu", "E", "entropy", "F"], True, 1e-8,
     "thermodynamics"),
    ("adiabatic/adiabaticity.csv", ["Q_max"], True, 1e-6, "adiabaticity Q_max"),
]
for table, columns, relative, tolerance, what in COMPARISONS:
    largest = worst(table, columns, relative)
    report(f"largest difference, {what}", f"{largest:.1e}")
    check(largest <= tolerance, f"{what} agree with the record within {tolerance:.0e}",
          record=f"{RECORD_RESULTS}/{table}")
```

`COMPARISONS` lists five comparisons, each a tuple (a fixed group of values in parentheses): the table, its columns, whether the comparison is relative, the tolerance (the values fixed in advance in `Revision/kohn_sham/reports/ks-rust-determinism.json`) and a description. The loop unpacks each tuple into five names, computes the largest difference, reports it and checks it. Out [6] reports 0.0 for all five and five PASS lines: on this computer the new numbers are exactly the recorded ones.

In [7], the ground states along the history.

```
ground = read_table(NEW_RESULTS, "ground/summary.csv")  # the 75 ground states
excited = read_table(NEW_RESULTS, "excited/summary.csv")  # their Delta-SCF

def state_id(n, tag, a4):
    return f"N{n}_{tag}_a{round(10 * a4):02d}"
```

From here on the notebook reads the new results. `state_id` builds the solver's name of a state: `round(10 * a4)` is ten times the slice as a whole number, and the format `02d` writes it with two digits, so $N = 136$, `lam0`, $a_{4,0} = 1$ gives `N136_lam0_a10`.

```
say("   N  a4,0        E_KS        HOMO        LUMO     KS gap")
for n in (8, 136, 688):
    for a4 in SLICES:
        row = ground[state_id(n, "lam0", a4)]
        say(f"{n:4d}  {a4:4.1f}  {float(row['E_KS']):10.5f}  {float(row['HOMO']):10.6f}"
            f"  {float(row['LUMO']):10.6f}  {float(row['KS_gap']):9.6f}")
report("KS gap of N = 8 at a4,0 = 0, 1, 2", ", ".join(
    f"{float(ground[state_id(8, 'lam0', a)]['KS_gap']):.7f}" for a in (0, 1, 2)))
```

For the three particle numbers without interaction and the five slices the cell prints a table of E_{KS}, the HOMO, the LUMO and the gap, and then the gap of $N = 8$ at $a_{4,0} = 0, 1, 2$ with seven digits. Out [7] is the table of Section 15.15. For $N = 8$ the energy is exactly 0 at every slice (the zero modes have $\varepsilon = 0$ and there is no interaction), and the gaps are 0.4307337, 0.1703493, 0.0641594.

In [8], the levels along the history.

```
def read_levels(n, tag, a4):
    path = NEW_RESULTS / "ground/levels" / f"{state_id(n, tag, a4)}.csv"
    with open(path, newline="", encoding="utf-8") as handle:
        return {(int(r["n2"]), int(r["j"]), r["parity"], int(r["label"])):
                (float(r["eps"]), float(r["f"])) for r in csv.DictReader(handle)}
```

`read_levels` reads the level table of one state and returns a dictionary whose key is the **key** of a level, the four numbers (shell n_2, block type j, parity, Pruefer label l), and whose value is the pair (level, occupation).

```
levels = [read_levels(136, "lam0", a4) for a4 in SLICES]  # one dictionary per slice
THEORY = json.loads(repository_file("Revision/kohn_sham/ks-theory.json").read_text(
    encoding="utf-8"))  # the theory file of the solver
C_SLOPE = float(THEORY["checksNumeric"]["braneBandSlope_M1_H1_L3_a0"])  # c
fig, ax = plt.subplots(figsize=(7.5, 5.0))
all_keys = sorted(set().union(*levels))
```

`levels` holds the level tables of $N = 136$, $\lambda = 0$ at the five slices. `C_SLOPE` is the band slope c from the theory file. `set().union(*levels)` is the set of all keys that occur at any slice (a **set** is a collection without repetitions), sorted into a list.

```
for key in all_keys:
    points = [(a4, lv[key]) for a4, lv in zip(SLICES, levels) if key in lv]
    xs = [p[0] for p in points]
    es = [p[1][0] for p in points]
    if min(es) > 1.6:
        continue  # only the part of the spectrum near the Fermi level
    band = key[1] == 1 and key[2] == "even" and key[3] == 0 and key[0] >= 1
    colour = PALETTE[0] if band else ("black" if key[0] == 0 else "0.6")
    ax.plot(xs, es, "-", color=colour, lw=1.0, alpha=0.8)
    for x, (e, f) in points:
        ax.plot([x], [e], "o", ms=5, color=colour,
                markerfacecolor=colour if f > 0.5 else "white")
```

For each key the cell collects the slices at which the level exists (the label sets differ a little from slice to slice) with its level and occupation. Levels that stay above $1.6\,m$ are skipped (`continue` jumps to the next key). A key belongs to the brane band if it is $j = +1$, even, label 0 and $n_2 \geq 1$; band levels are drawn blue, levels at $k = 0$ black and all others grey. Each level is drawn as a thin line through its points, and each point as a dot that is filled when the level is occupied ($f > 0.5$) and open (white inside) when it is empty.

```
a_fine = np.linspace(0.0, 2.0, 101)
ax.plot(a_fine, C_SLOPE * 0.25 * np.exp(-a_fine), "--", color=PALETTE[1], lw=1.5,
        label="$c\\,k\\,e^{-a_{4,0}}$ for $k = 0.25$")
ax.plot([], [], "o-", color=PALETTE[0], label="brane band ($j=+1$, even, $l=0$)")
ax.plot([], [], "o-", color="black", label="levels at $k = 0$")
ax.plot([], [], "o-", color="0.6", label="other levels")
ax.plot([], [], "o", color="0.3", markerfacecolor="white", label="open: empty")
ax.set_ylim(-0.05, 1.6)
```

```
ax.set_xlabel("slice $a_{4,0}$ of the history")
ax.set_ylabel("level $\\varepsilon$ (units of $m$)")
ax.set_title("Kohn-Sham levels of $N = 136$, $\\lambda = 0$, along the history")
ax.legend(fontsize=8, loc="center right")
save_figure(fig, "levels_history",
            "Kohn-Sham levels $\\varepsilon$ (vertical axis, units of $m$) of the "
...)
```

`a_fine` holds 101 slices from 0 to 2; the dashed orange curve is the small-k law $c\,k\,e^{-a_{4,0}}$ for the first shell. The empty plots make the legend entries, and the remaining lines set the range, labels and title and save Figure 15a.1.

```
k0_keys = [key for key in levels[0] if key[0] == 0]
k0_spread = max(abs(lv[key][0] - levels[0][key][0]) for lv in levels for key in k0_keys)
band_keys = [key for key in all_keys if all(key in lv for lv in levels)
             and key[1] == 1 and key[2] == "even" and key[3] == 0 and key[0] >= 1]
decreasing = all(levels[i + 1][key][0] < levels[i][key][0]
                 for key in band_keys for i in range(4))
report("number of brane-band levels followed through all five slices", len(band_keys))
check(k0_spread <= 1e-12, "the k = 0 levels are the same at every slice")
check(decreasing, "every brane-band level decreases strictly along the history")
```

`k0_spread` is the largest change of a level at $k = 0$ between the first slice and any other. `band_keys` are the band levels present at all five slices, and `decreasing` is true when each of them is lower at each slice than at the previous one (`all(...)` is true when every comparison is true). Out [8]: 8 band levels are followed through all slices, the $k = 0$ levels do not move, and every band level falls; both are consequences of the rescaling identity (Section 15.4). In Figure 15a.1 the lowest blue level (the first shell) lies below the dashed curve at $a_{4,0} = 0$, where the momentum 0.25 is not yet small enough for the straight-line law, and approaches it along the history as the redshifted momentum shrinks.

In [9], the gaps.

```
fig, ax = plt.subplots()
for colour, n in zip(PALETTE, (8, 136, 688)):
    gaps = [float(ground[state_id(n, "lam0", a4)]["KS_gap"]) for a4 in SLICES]
    ax.plot(SLICES, gaps, "o-", color=colour, lw=1.5, label=f"$N = {n}$")
    ax.plot(a_fine, gaps[0] * np.exp(-a_fine), "--", color=colour, lw=1.0)
ax.set_yscale("log")
ax.set_xlabel("slice $a_{4,0}$ of the history")
ax.set_ylabel("Kohn-Sham gap $\\Delta_{KS}$ (units of $m$)")
ax.set_title("The gap closes along the history (dashed: $\\propto e^{-a_{4,0}}$)")
ax.legend()
save_figure(fig, "gaps_history",
            "Kohn-Sham gap $\\Delta_{KS}$ (vertical axis, logarithmic, units of $m$) "
...)
```

For each particle number the gaps at the five slices are drawn as dots joined by lines, with a dashed curve $\Delta(0)\,e^{-a_{4,0}}$ through the first point; `set_yscale("log")` makes the vertical axis logarithmic, on which $e^{-a_{4,0}}$ is a straight line. This is Figure 15a.2.

```
free_dscf = max(abs(float(excited[state_id(n, "lam0", a)]["delta_SCF_minus_gap"]))
                for n in (8, 136, 688) for a in SLICES)
report("largest |Delta-SCF - gap| without interaction", f"{free_dscf:.1e}")
check(free_dscf <= 1e-10, "Delta-SCF equals the gap without interaction",
      record=f"{RECORD_REPORT}, check excited_delta_scf_free_equals_gap")
shrinking = all(float(ground[state_id(n, "lam0", SLICES[i + 1])]["KS_gap"])
                < float(ground[state_id(n, "lam0", SLICES[i])]["KS_gap"])
                for n in (8, 136, 688) for i in range(4))
check(shrinking, "every gap shrinks from slice to slice")
```

`free_dscf` is the largest $|\Delta_{SCF} - \Delta_{KS}|$ of the 15 free states; Out [9] gives 2.0×10^{-11}, the value of the record's check, below its tolerance 10^{-10}. The second check confirms that every gap shrinks from slice to slice.

In [10], the orbital relaxation.

```
fig, axes = plt.subplots(1, 3, figsize=(10.0, 3.8), sharey=True,
                         layout="constrained")
for ax, n in zip(axes, (8, 136, 688)):
    for colour, tag, label in zip(PALETTE, ("lamp1", "lamm1", "lamp2", "lamm2"),
                                  ("$+\\lambda_1$", "$-\\lambda_1$", "$+\\lambda_2$",
                                   "$-\\lambda_2$")):
        diff = [float(excited[state_id(n, tag, a)]["delta_SCF_minus_gap"])
                for a in SLICES]
        ax.plot(SLICES, diff, "o-", color=colour, lw=1.5, label=label)
    ax.set_yscale("symlog", linthresh=1e-9)
    ax.set_title(f"$N = {n}$")
    ax.set_xlabel("slice $a_{4,0}$")
axes[0].set_ylabel("$\\Delta_{SCF} - \\Delta_{KS}$ (units of $m$)")
axes[0].legend(fontsize=8)
```

Three panels, one per particle number; in each, the relaxation $\Delta_{SCF} - \Delta_{KS}$ of the four interacting couplings at the five slices. The **symmetric logarithmic** axis (`"symlog"`) is logarithmic for large values of either sign and linear between -10^{-9} and 10^{-9} (`linthresh`), so that small values of both signs fit on one axis.

```
largest_id = max(excited, key=lambda i: abs(float(excited[i]["delta_SCF_minus_gap"])))
largest_relax = abs(float(excited[largest_id]["delta_SCF_minus_gap"]))
mantissa, power = f"{largest_relax:.1e}".split("e")  # e.g. "5.5", "-04"
save_figure(fig, "delta_scf",
            "Orbital relaxation: the Delta-SCF excitation energy minus the Kohn-Sham "
...)
report("largest |Delta-SCF - gap| over the 75 states",
       f"{largest_relax:.3e} ({largest_id})")
check(largest_id == "N688_lamp2_a00",
      "the largest relaxation belongs to N = 688, +lambda_2, a4,0 = 0 (the caption)")
check(largest_relax < 1e-3, "the orbital relaxation is below 0.001 m in every state")
```

`max(excited, key=...)` returns the state name whose relaxation has the largest size. The number is written in the format `.1e` and split at the letter e into the digits and the power of ten, which the

caption of Figure 15a.3 prints as 5.5×10^{-4} (so the caption's number is computed, not typed). Out [10]: the largest relaxation is $5.496 \times 10^{-4}\,m$, in `N688_lamp2_a00`, where the lowest empty level is the bulk level at $k = 0$, and every relaxation is below $0.001\,m$.

In [11], the total energy.

```
fig, (left, right) = plt.subplots(1, 2, figsize=(10.0, 4.0), layout="constrained")
for colour, n in zip(PALETTE, (136, 688)):
    energies = [float(ground[state_id(n, "lam0", a)]["E_KS"]) for a in SLICES]
    left.plot(SLICES, energies, "o-", color=colour, lw=1.5, label=f"$N = {n}$")
left.set_yscale("log")
left.set_xlabel("slice $a_{4,0}$")
left.set_ylabel("$E_{KS}$ (units of $m$)")
left.set_title("Energy without interaction")
left.legend()
```

The left panel draws E_{KS} of the free states $N = 136$ and 688 at the five slices on a logarithmic axis.

```
tags = ("lamp2", "lamp1", "lamm1", "lamm2")
labels = ("$+\\lambda_2$", "$+\\lambda_1$", "$-\\lambda_1$", "$-\\lambda_2$")
largest_shift = 0.0  # the largest |E(lambda) - E(0)| of N = 136
for colour, tag, label in zip(PALETTE, tags, labels):
    shift = [float(ground[state_id(136, tag, a)]["E_KS"])
             - float(ground[state_id(136, "lam0", a)]["E_KS"]) for a in SLICES]
    largest_shift = max([largest_shift] + [abs(s) for s in shift])
    right.plot(SLICES, shift, "o-", color=colour, lw=1.5, label=label)
e136 = [float(ground[state_id(136, "lam0", a)]["E_KS"]) for a in SLICES]
right.axhline(0.0, color="0.4", lw=0.8)
right.set_xlabel("slice $a_{4,0}$")
right.set_ylabel("$E_{KS}(\\lambda) - E_{KS}(0)$ (units of $m$)")
right.set_title("Interaction energy shift, $N = 136$")
right.legend(fontsize=8)
save_figure(fig, "energy_history",
            "Left: the Kohn-Sham energy $E_{KS}$ (vertical axis, logarithmic, units "
...)
```

The right panel draws, for $N = 136$, the change $E_{KS}(\lambda) - E_{KS}(0)$ of the four couplings at the five slices, and keeps the largest size of these changes in `largest_shift` (the list `[largest_shift] + [...]` joins the old largest value with the new sizes). `e136` are the free energies of $N = 136$; the caption of Figure 15a.4 prints their smallest and largest value and `largest_shift`.

```
report("largest |E(lambda) - E(0)| of N = 136", f"{largest_shift:.4f}")
ordered = all(
    float(ground[state_id(n, "lamp2", a)]["E_KS"])
    > float(ground[state_id(n, "lamp1", a)]["E_KS"])
    > float(ground[state_id(n, "lam0", a)]["E_KS"])
    > float(ground[state_id(n, "lamm1", a)]["E_KS"])
    > float(ground[state_id(n, "lamm2", a)]["E_KS"])
    for n in (136, 688) for a in SLICES)
check(ordered, "E(+lambda2) > E(+lambda1) > E(0) > E(-lambda1) > E(-lambda2), "
               "N = 136 and 688")
```

```
falling = all(float(ground[state_id(n, "lam0", SLICES[i + 1])]["E_KS"])
              < float(ground[state_id(n, "lam0", SLICES[i])]["E_KS"])
              for n in (136, 688) for i in range(4))
check(falling, "the energy of N = 136 and 688 falls from slice to slice")
```

Out [11]: the largest shift is $0.0318\,m$, out of energies from 12 to $80\,m$. Python allows a chain of comparisons, `a > b > c`, which is true when every neighbouring pair is ordered; the first check confirms that repulsion raises and attraction lowers the energy, more for the stronger coupling, at every slice for $N = 136$ and 688. The second confirms that the free energies fall from slice to slice. For $N = 8$ the order is reversed (the text cell before the code cell explains why, and Section 15.5 gives the exact symmetry).

In [12], the densities.

```
VOL7 = (2.0 * math.pi / 0.25) ** 3  # proper 7-volume per unit e^{6Hy} (v_t = 1)

def read_profile(n, tag, a4):
    path = NEW_RESULTS / "ground/profiles" / f"{state_id(n, tag, a4)}.csv"
    data = np.genfromtxt(path, delimiter=",", names=True)
    return {name: data[name] for name in data.dtype.names}
```

`read_profile` reads the profile table of a state with `np.genfromtxt`, which turns a CSV file into an array whose columns can be addressed by the names in the first line (`names=True`); the function returns a dictionary from each column name (`y`, `n`, `S`, `M_eff`, `v_v`, `rho`, `p3`, ...) to its array of 151 values.

```
def simpson(values, step):
    weights = np.full(len(values), 2.0)
    weights[1::2] = 4.0
    weights[0] = weights[-1] = 1.0
    return step / 3.0 * float(np.sum(weights * values))
```

`simpson` is Simpson's rule for an odd number of equally spaced values: weights 1, 4, 2, 4, ..., 4, 1 times $h/3$ (`np.full(n, 2.0)` is an array of n twos).

```
fig, (left, right) = plt.subplots(1, 2, figsize=(10.0, 4.0), layout="constrained")
counts = []
for shade, a4 in zip((SLICE_SHADES[0], SLICE_SHADES[2], SLICE_SHADES[4]), (0, 1, 2)):
    prof = read_profile(136, "lam0", a4)
    y = prof["y"]
    per_y = 2.0 * VOL7 * np.exp(6.0 * y) * prof["n"]  # particles per unit y
    counts.append(simpson(per_y, y[1] - y[0]))
    left.plot(y, prof["n"], color=shade, lw=1.8, label=f"$a_{{4,0}} = {a4}$")
    right.plot(y, per_y, color=shade, lw=1.8, label=f"$a_{{4,0}} = {a4}$")
```

For $N = 136$, $\lambda = 0$ at the slices 0, 1, 2 the cell reads the profile, forms the number of particles per unit y in the doubled box, $2\,\mathrm{Vol}_7\, e^{6Hy} n(y)$, integrates it with Simpson's rule (the spacing is `y[1] - y[0]` $= 0.02$), and draws the proper density on the left and the particles per unit y on the right.

```
left.set_yscale("log")
left.set_xlabel("hidden coordinate $y$ (tip at $-3$, brane at $0$)")
left.set_ylabel("proper density $n(y)$")
left.set_title("Proper number density")
right.set_xlabel("hidden coordinate $y$")
right.set_ylabel("particles per unit $y$")
right.set_title("$2\\,\\mathrm{Vol}_7\\, e^{6Hy} n(y)$, area $= N$")
right.legend()
save_figure(fig, "densities",
            "Left: the proper number density $n(y)$ (vertical axis, logarithmic, "
...)
report("particle number from the profiles at a4,0 = 0, 1, 2",
       ", ".join(f"{c:.6f}" for c in counts))
check(max(abs(c - 136.0) for c in counts) < 1e-5,
      "Simpson's rule on the profiles gives N = 136 at every slice",
      record=f"{RECORD_REPORT}, check ground_N_conservation")
```

After the labels, `save_figure` saves Figure 15a.5. Out [12] gives 136.000002 at all three slices: the integral of the coarse 151-point profile reproduces N to 2×10^{-6} (the solver's own check ground_N_conservation, on its fine grid, gives 1.5×10^{-15}).

In [13], the self-consistent potentials.

```
fig, (left, right) = plt.subplots(1, 2, figsize=(10.0, 4.0), layout="constrained")
ratios = []  # profile maximum / recorded maximum, one per slice
for shade, a4 in zip(SLICE_SHADES, SLICES):
    prof = read_profile(136, "lamp2", a4)
    left.plot(prof["y"], prof["M_eff"] - 1.0, color=shade, lw=1.8,
              label=f"$a_{{4,0}} = {a4}$")
    right.plot(prof["y"], prof["v_v"], color=shade, lw=1.8)
    recorded = float(ground[state_id(136, "lamp2", a4)]["max_abs_Meff_minus_m"])
    ratios.append(float(np.max(np.abs(prof["M_eff"] - 1.0))) / recorded)
```

For $N = 136$ with $+\lambda_2$ the cell draws $M - m$ (left) and v (right) at the five slices, and for each slice divides the largest $|M - m|$ on the 151 profile points by the largest value that the solver recorded on its 1801 fine points.

```
left.set_xlabel("hidden coordinate $y$")
left.set_ylabel("$M(y) - m$ (units of $m$)")
left.set_title("Mass shift, $N = 136$, $+\\lambda_2$")
left.legend(fontsize=8)
right.set_xlabel("hidden coordinate $y$")
right.set_ylabel("$v(y)$ (units of $m$)")
right.set_title("Exchange potential, $N = 136$, $+\\lambda_2$")
m_max = [float(ground[state_id(136, "lamp2", a4)]["max_abs_Meff_minus_m"])
         for a4 in SLICES]  # the solver's largest |M - m| at each slice
v_max = [float(ground[state_id(136, "lamp2", a4)]["max_abs_v_v"]) for a4 in SLICES]
peak = int(np.argmax(m_max))  # the slice where |M - m| is largest
save_figure(fig, "potentials",
            "The self-consistent mass shift $M(y) - m$ (left) and potential $v(y)$ "
...)
```

`m_max` and `v_max` are the recorded largest $|M - m|$ and $|v|$ at the five slices, and `np.argmax` gives the position of the largest entry of `m_max`. The caption of Figure 15a.6 prints these numbers.

```
report("profile maximum / recorded maximum of |M - m|",
       ", ".join(f"{r:.5f}" for r in ratios))
check(all(0.998 <= r <= 1.0 + 1e-12 for r in ratios),
      "the profile maxima of |M - m| lie within 0.2 percent below the recorded ones",
      record=f"{RECORD_RESULTS}/ground/summary.csv, column max_abs_Meff_minus_m")
report("largest |M - m| at the five slices", ", ".join(f"{v:.3f}" for v in m_max))
report("largest |v| at the five slices", ", ".join(f"{v:.3f}" for v in v_max))
check(all(v_max[i + 1] > v_max[i] for i in range(4)) and SLICES[peak] == 1.5
      and max(m_max + v_max) < 0.4,
      "|v| grows at every slice, |M - m| peaks at a4,0 = 1.5, both stay below 0.4 m",
      record=f"{RECORD_RESULTS}/ground/summary.csv, columns max_abs_Meff_minus_m "
             "and max_abs_v_v")
```

Every profile point is also a point of the fine grid, so the profile maximum cannot exceed the recorded one; it is smaller when the true maximum lies between two profile points. Out [13]: the ratios lie between 0.99891 and 0.99997; the largest $|M - m|$ is 0.008, 0.050, 0.192, 0.355, 0.310 m and the largest $|v|$ is 0.015, 0.021, 0.059, 0.157, 0.242 m at the five slices. Both checks pass (`m_max + v_max` joins the two lists into one).

In [14], the convergence of the loop.

```
runs = json.loads((NEW_RESULTS / "ground/runs.json").read_text(encoding="utf-8"))
by_id = {run["id"]: run for run in runs}
fig, ax = plt.subplots()
styles = {"lamp2": "-", "lamm2": "--"}
for colour, n in zip(PALETTE, (8, 136, 688)):
    for tag, style in styles.items():
        history = by_id[state_id(n, tag, 2.0)]["scfHistory_iteration_residual_E"]
        ax.plot([h[0] for h in history], [h[1] for h in history], style, marker="o",
                ms=4, color=colour, lw=1.5,
                label=f"$N = {n}$, {'+' if tag == 'lamp2' else '-'}$\\lambda_2$")
```

`runs.json` is a list with one entry per ground state; `by_id` files them under their names. For the strongest couplings $\pm\lambda_2$ at the last slice (the hardest cases) the residual of every iteration is drawn, solid for $+\lambda_2$ and dashed for $-\lambda_2$.

```
ax.axhline(1e-11, color="0.3", ls=":", lw=1.2, label="tolerance $10^{-11}$")
ax.set_yscale("log")
ax.set_xlabel("iteration")
ax.set_ylabel("residual: largest change of the potential (units of $m$)")
ax.set_title("Anderson mixing, $a_{4,0} = 2$, couplings $\\pm\\lambda_2$")
ax.legend(fontsize=8, ncol=2)
save_figure(fig, "scf_convergence",
            "Convergence of the self-consistent loop with Anderson mixing: the "
...)
direct = all(run["path"] == "direct" for run in runs)
final = max(run["scfHistory_iteration_residual_E"][-1][1] for run in runs)
longest = max(run["iterations"] for run in runs)
```

```
report("largest final residual / largest number of iterations",
       f"{final:.2e} / {longest}")
check(len(runs) == 75 and direct and final <= 1e-11,
      "all 75 ground states converged directly below the tolerance 1e-11",
      record=f"{RECORD_REPORT}, check ground_scf_converged")
```

After the tolerance line and the labels (`ncol=2` puts the legend in two columns), `save_figure` saves Figure 15a.7. `direct` is true when every run took the path `direct` (no fallback was needed), `final` is the largest last residual and `longest` the largest number of iterations. Out [14]: 9.34×10^{-12} and 17, and the check passes. In the figure the curves of $N = 8$ for $+\lambda_2$ and $-\lambda_2$ coincide, as the exact symmetry of Section 15.5 predicts.

In [15], the particle-hole excitations.

```
TAGS = ("lam0", "lamp1", "lamm1", "lamp2", "lamm2")  # the five couplings

def read_pairs(n, tag, a4):
    path = NEW_RESULTS / "excited/particle-hole" / f"{state_id(n, tag, a4)}.csv"
    with open(path, newline="", encoding="utf-8") as handle:
        return {(r["hole_levels"], r["particle_levels"]):
                (float(r["delta_eps"]), float(r["multiplicity"]), r["same_sector"])
                for r in csv.DictReader(handle)}

lists = {(n, tag, a4): read_pairs(n, tag, a4)
         for n in (8, 136, 688) for tag in TAGS for a4 in SLICES}  # 75 states
```

`read_pairs` reads the list of the lowest particle-hole excitations of a state: the key is the pair (hole levels, particle levels), each written `n2:j:parity:label`, and the value is the excitation energy $\Delta\varepsilon = \varepsilon_{particle} - \varepsilon_{hole}$, the multiplicity $g_{hole}\, g_{particle}$ and the word `true` or `false` that says whether the two levels lie in the same sector. `lists` holds these lists for all 75 ground states.

```
fig, ax = plt.subplots()
for a4 in SLICES:
    values = list(lists[(136, "lam0", a4)].values())
    ax.scatter([a4] * len(values), [v[0] for v in values],
               s=[v[1] / 40.0 for v in values],  # marker area ~ multiplicity
               color=PALETTE[0], alpha=0.3, edgecolors=PALETTE[0])
lowest = [min(v[0] for v in lists[(136, "lam0", a4)].values()) for a4 in SLICES]
ax.plot(SLICES, lowest, "o-", color=PALETTE[1], lw=1.8, ms=5,
        label="lowest excitation (the Kohn-Sham gap)")
ax.plot(a_fine, lowest[0] * np.exp(-a_fine), "--", color="0.4", lw=1.0,
        label="$\\propto e^{-a_{4,0}}$")
```

`ax.scatter` draws markers whose areas are given by `s`: here the multiplicity divided by 40, so a larger marker is a more degenerate excitation. For $N = 136$ without interaction all listed excitations are drawn at their slice, the lowest excitation of each slice is joined by an orange line, and a dashed curve falls like $e^{-a_{4,0}}$ from the first one.

```
ax.scatter([], [], s=60, color=PALETTE[0], alpha=0.3, edgecolors=PALETTE[0],
           label="excitations (area: multiplicity)")
ax.set_yscale("log")
ax.set_xlabel("slice $a_{4,0}$ of the history")
ax.set_ylabel("excitation energy $\\Delta\\varepsilon$ (units of $m$)")
ax.set_title("Particle-hole excitations of $N = 136$, $\\lambda = 0$")
ax.legend(fontsize=8, loc="lower left")
save_figure(fig, "particle_hole",
            "The lowest particle-hole excitation energies (vertical axis, "
...)
```

A legend entry, the axes and `save_figure` for Figure 15a.8.

```
lowest_is_gap = all(
    abs(min(v[0] for v in lists[key].values())
        - float(ground[state_id(*key)]["KS_gap"])) <= 1e-12 for key in lists)
cheaper = True
for n in (8, 136, 688):
    for tag in TAGS:
        series = [lists[(n, tag, a4)] for a4 in SLICES]
        common = set(series[0]).intersection(*series[1:])  # listed at every slice
        cheaper = cheaper and all(series[i + 1][key][0] < series[i][key][0]
                                  for key in common for i in range(4))
```

`lowest_is_gap` is true when in every state the lowest listed excitation equals the Kohn-Sham gap (`state_id(*key)` unpacks the triple $(N, \text{tag}, a_{4,0})$ into the three arguments). For each of the 15 series (particle number and coupling), `common` is the set of excitations listed at all five slices (`intersection` keeps what all sets share), and `cheaper` stays true only if each of them is cheaper at each slice than at the previous one.

```
count = sum(len(pairs) for pairs in lists.values())
inside = sum(1 for pairs in lists.values() for v in pairs.values() if v[2] != "false")
jumps = [float(row["Q_max_delta_eps"]) for row in
         read_table(NEW_RESULTS, "adiabatic/adiabaticity.csv").values()
         if row["Q_max_delta_eps"] != "null"]  # null: no jump (N = 8)
report("particle-hole excitations listed / inside one sector", f"{count} / {inside}")
report("lowest excitation of N = 136 at a4,0 = 0 and 2",
       f"{lowest[0]:.5f}, {lowest[-1]:.5f}")
report("energy of the largest-Q jump inside a sector (smallest, largest)",
       f"{min(jumps):.3f}, {max(jumps):.3f}")
```

`count` is the number of listed excitations of all 75 states, and `inside` the number of those whose two levels lie in one sector. `jumps` collects, from the adiabaticity table, the energy of the jump with the largest adiabaticity number Q in each state (Section 15.21); for $N = 8$ there is no such jump and the table says `null`. Out [15]: 1610 excitations, none inside one sector; the lowest excitation of $N = 136$ falls from 0.08267 to 0.01446; the in-sector jumps cost between 1.488 and 2.253 m.

```
check(lowest_is_gap, "in all 75 states the lowest particle-hole energy is the KS gap",
      record=f"{RECORD_RESULTS}/excited/particle-hole and ground/summary.csv")
```

```
check(cheaper, "every excitation listed at all five slices gets cheaper along the "
               "history")
check(count >= len(lists) and inside == 0,
      f"none of the {count} listed excitations stays inside one sector",
      record=f"{RECORD_RESULTS}/excited/particle-hole, column same_sector")
```

The three checks pass. The meaning of the third: the exact evolution along the history keeps the momentum, the block type and the parity of every orbital (Section 15.21), so the motion of the background alone cannot create any of the 1610 excitations; it can only cause jumps inside a sector, and the jump with the largest Q costs between $1.488\,m$ and $2.253\,m$.

In [16], the last check.

```
NAMES = ["levels_history", "gaps_history", "delta_scf", "energy_history",
         "densities", "potentials", "scf_convergence",
         "particle_hole"]  # the figures, in order
missing = [name for number, name in enumerate(NAMES, start=1)
           if not output_file(f"{FIGURE_FOLDER}/15a_{number}_{name}.png").is_file()]
check(missing == [], "every figure file of this notebook exists")
all_checks_passed()
```

The same as In [15] of Notebook 15e (Section 15.9), with the eight figure names of this notebook in order (the comment says so) and the file names `15a_<number>_<name>.png`: `enumerate(NAMES, start=1)` pairs each name with its number, the list comprehension collects the names whose file does not exist, the check requires that list to be empty, and `all_checks_passed()` prints the last line. The cell prints PASS every figure file of this notebook exists and ALL 25 CHECKS PASSED (notebook 15a).

15.15 What the canonical matrix shows

All numbers of this section are COMPUTED by the Rust solver and reproduced by Notebook 15a; the cell is named with each.

The ground states without interaction (Notebook 15a, Out [7]; `Revision/kohn_sham/results/ground/summary.csv`):

N	$a_{4,0}$	E_{KS}	**HOMO**	**LUMO**	Δ_{KS}
8	0	0	0	0.430734	0.430734
8	1	0	0	0.170349	0.170349
8	2	0	0	0.064159	0.064159
136	0	80.28222	0.799646	0.882320	0.082674
136	1	32.38412	0.325768	0.360757	0.034989
136	2	12.44507	0.126766	0.141223	0.014457
688	0	680.44125	1.247113	1.292293	0.045180
688	1	279.42489	0.515229	0.535712	0.020484
688	2	110.38667	0.205760	0.214370	0.008610

How to read it. For $N = 8$ the eight particles sit in the zero modes at $\varepsilon = 0$, so $E_{KS} = 0$ at every slice, and the gap is the first band level (Section 15.4). For $N = 136$ the HOMO is the band level of

the shell $n_2 = 4$ and the LUMO that of $n_2 = 5$; both redshift, and the energy, the sum of $g\varepsilon$ over the occupied band levels, falls from 80.28 to 12.45, by a factor 6.45. For $N = 688$ at $a_{4,0} = 0$ the LUMO is 1.292293, the bulk level at $k = 0$, which does not move; at later slices the band levels of the shells 12 and higher have come down below it, and the LUMO is again a band level. (Section 15.21 shows that a filling of $N = 696$ would cross the Fermi level for this reason.)

The gaps close more slowly than $e^{-a_{4,0}}$. Figure 15a.2 shows all gaps falling, each a little more slowly than its dashed line. The reason is the bending of the band (Section 15.4 and Exercise 2): a gap is the distance between two band levels, and a band level falls exactly like $e^{-a_{4,0}}$ only where it is a straight line, at small redshifted momenta.

Delta-SCF and the orbital relaxation. Without interaction $\Delta_{SCF} = \Delta_{KS}$ to $2.0 \times 10^{-11}\, m$ (Out [9]). With interaction the relaxation $\Delta_{SCF} - \Delta_{KS}$ is at most $5.5 \times 10^{-4}\, m$ (Out [10], `N688_lam p2_a00`), in every state far below the gap itself: the first excited state is well described by moving one particle between frozen orbitals.

The interaction is a perturbation. For $N = 136$ the couplings change the energy by at most $0.0318\, m$ (Out [11]), and the self-consistent potentials stay below $0.4\, m$ (Out [13]). The potentials grow along the history (the largest $|v|$ from 0.015 to $0.242\, m$ for $+\lambda_2$), as the calibration of Section 15.2 anticipated, and they live near the tip, where the proper densities are large (Figure 15a.6). All this holds at the cutoff $L = 3$, where the couplings were calibrated; at larger L the interaction effects grow: for $N = 136$ at $a_{4,0} = 2$ the shift of the energy by $-\lambda_1$ is at large L about 21 times its size at $L = 3$, and the shift by $+\lambda_1$ is at $L = 5.5$, the last L before its iteration fails, about 28 times its size at $L = 3$; its limit is not established (Section 15.2, the paragraph on the cutoff). The self-consistent loop converged directly in all 75 states in at most 17 iterations (Out [14]).

Where the particles are. Figure 15a.5 makes the most important picture of the gas visible: the particles themselves sit near the brane (right panel), but the proper density, particles per proper 7-volume, is largest at the tip (left panel), because the proper volume factor e^{6Hy} is tiny there ($e^{-18} = 1.5 \times 10^{-8}$ at $y = -3$). Along the history the redshifted band orbitals reach further toward the tip.

Excitations. In every state the cheapest way to excite the gas is the Kohn-Sham gap, all listed excitations get cheaper along the history, and none of them can be caused by the history alone (Out [15]); the next sections ask how much energy the history does put into the gas (Section 15.16) and how strongly it can disturb it (Section 15.21).

What this does not show. These are instantaneous states on a PRESCRIBED background, with the ASSUMED brane and the CONVENTION of filling. Whether a real gas follows them along the history is the question of adiabaticity (Section 15.21); whether the gas could make the history itself is answered in Section 15.16: it could not.

15.16 The energy-momentum tensor of the gas, and why the gas cannot drive the history

What the tensor is. Chapter 9 introduced the **energy-momentum tensor** $T^{\mu}{}_{\nu}$: at every point a table of 8×8 numbers that says how much energy and momentum there is and how it flows. For the Kohn-Sham states it is diagonal, and its diagonal holds the **energy density** $\rho = -T^{x_4}{}_{x_4}$ and the **pressures** $p_\mu = T^{\mu}{}_{\mu}$ (no sum over μ; the sign convention of the Revision record). Because of the symmetries of the states only four different numbers occur at each y: p_3, the pressure along

each of the three directions of 3-space; p_t, the pressure along each of the three extra times; p_0, the pressure along the hidden direction; and ρ. They are proper densities (per proper 7-volume) and depend on y.

The formulas (ks-theory.json, emt; checks emt_orbital_components and emt_trace_identity). With the orbital densities $n_o = P(a^2+b^2)$, $s_o = P\,j\,2ab$ and $t_o = P\,j\,(a^2-b^2)$ (the last one is the current along the momentum; $P = e^{-6Hy}/\mathrm{Vol}_7$ as in Section 15.2) and sums over the occupied levels with the weights wgf:

$$\rho = \sum wgf\,\varepsilon\,n_o - e_{int}, \qquad p_3 = \sum wgf\,\tfrac{\kappa k}{3}\,t_o + e_{int}, \qquad p_t = e_{int},$$

$$p_0 = \sum wgf\,[(\varepsilon - v)\,n_o - M s_o - \kappa k\,t_o] + e_{int}.$$

Three remarks make these formulas plausible. (1) The energy density is the level times the number density, summed, minus the interaction energy density (the same double counting as in Section 15.5). (2) A quantum moving along x_1 pushes on a wall across x_1 with $\kappa k\,t_o$; a closed shell of momenta contains every direction equally often (a cube has the same number of vectors along each axis), so the pressure along each of the three directions is one third of it. (3) The states belong to the **good sector**: they have no momentum along the extra times, so the extra-time pressure has no kinetic part at all, and only the interaction contributes, $p_t = e_{int}$. Without interaction $p_t = 0$.

The conservation law along the hidden direction. The conservation law of the tensor states that its covariant divergence vanishes, $\nabla_\mu T^\mu{}_\nu = 0$ (Chapter 9). In flat spacetime it says that energy and momentum are neither created nor destroyed, they only flow. In the author's metric, which depends on the time x_4 through a_4, it is a local balance law: the energy of the gas is not conserved, it changes along the history (the energy-change law below; for a universe, Section 20.22 (d)). We write out its y component for a diagonal tensor that depends only on y, line by line. The covariant divergence of a mixed tensor is

$$\nabla_\mu T^\mu{}_\nu = \partial_\mu T^\mu{}_\nu + \Gamma^\mu{}_{\mu\sigma} T^\sigma{}_\nu - \Gamma^\sigma{}_{\mu\nu} T^\mu{}_\sigma,$$

with the Christoffel symbols Γ (Chapters 3 and 9; summed over repeated indices). For a diagonal metric Chapter 9 gives $\Gamma^\lambda{}_{\mu\nu} = \frac{1}{2g_{\lambda\lambda}}(\partial_\mu g_{\lambda\nu} + \partial_\nu g_{\lambda\mu} - \partial_\lambda g_{\mu\nu})$ (no sum over λ).

$$\nabla_\mu T^\mu{}_y = \partial_y T^y{}_y + \Gamma^\mu{}_{\mu y}\,T^y{}_y - \sum_\nu \Gamma^\nu{}_{\nu y}\,T^\nu{}_\nu.$$

Rule: set $\nu = y$; for a diagonal tensor only $\sigma = y$ survives in the middle term and only $\sigma = \mu$ in the last, and only the y derivative of $T^y{}_y$ is nonzero. (The index ν in the sum runs over the eight directions; the letter λ is kept for the coupling.)

$$\Gamma^\mu{}_{\mu y} = \partial_y \ln\sqrt{|g|} = \partial_y(6Hy) = 6H.$$

Rule: for a diagonal metric $\Gamma^\mu{}_{\mu y} = \sum_\mu \frac{1}{2g_{\mu\mu}}\partial_y g_{\mu\mu} = \frac{1}{2}\sum_\mu \partial_y \ln|g_{\mu\mu}| = \frac{1}{2}\partial_y \ln|\det g| = \partial_y \ln\sqrt{|g|}$ (the formula above with $\lambda = \mu$ and $\nu = y$, where the first and the last term cancel; $\partial \ln Q = \partial Q/Q$; the logarithm of a product is the sum of the logarithms), and $\sqrt{|g|} = e^{6Hy}$ (Chapter 14).

$$\Gamma^{\nu}{}_{\nu y} = \tfrac{1}{2} g^{\nu\nu}\partial_y g_{\nu\nu} = \tfrac{1}{2}\partial_y \ln|g_{\nu\nu}| = H \quad (\nu = x_1, x_2, x_3, x_5, x_6, x_7), \qquad \Gamma^{x_4}{}_{x_4 y} = \Gamma^{y}{}_{yy} = 0.$$

Rule: the same formula for one value of ν (no sum) gives half the derivative of $\ln|g_{\nu\nu}|$; the six warped directions carry the factor e^{2Hy} in the line element $ds^2 = e^{2Hy}[e^{2a_4}(dx_1^2 + dx_2^2 + dx_3^2) - e^{-2a_4}(dx_5^2 + dx_6^2 + dx_7^2)] - dx_4^2 + dy^2$, and $\tfrac{1}{2}\partial_y \ln e^{2Hy} = H$; $g_{x_4x_4} = -1$ and $g_{yy} = 1$ are constant.

$$p_0' + 6H\,p_0 - 3H\,p_3 - 3H\,p_t = 0.$$

Rule: $T^{y}{}_{y} = p_0$; the six warped terms give H times p_3 three times and H times p_t three times.

$$(e^{6Hy}p_0)' = 3H\,e^{6Hy}\,(p_3 + p_t).$$

Rule: $(e^{6Hy}p_0)' = e^{6Hy}(p_0' + 6Hp_0)$ (product and chain rule); multiply the previous line by e^{6Hy}. This is the **conservation law along** y (ks-theory.json, emt.conservationY). Integrated from the tip to the brane it reads $[e^{6Hy}p_0]_{-L}^{0} = 3H\int_{-L}^{0} e^{6Hy}(p_3 + p_t)\,dy$. It is PROVED for every self-consistent state (check emt_y_conservation_selfconsistent of `Revision/kohn_sham/reports/ks-theory-python.json`: the force terms $-M'S - v'n$ of the orbitals cancel exactly against the derivative of e_{int} when the potentials are the self-consistent ones) and COMPUTED for all 75 ground states of the record (checks emt_y_conservation_pointwise, worst relative residual 1.95×10^{-8}, and emt_y_conservation_integrated, worst 1.42×10^{-11}, of `Revision/kohn_sham/reports/ks-rust-solver.json`).

The energy change along the history. Now the x_4 component. The metric depends on x_4 through $a_4(x_4)$, and the states are instantaneous states that follow it. Line by line:

$$\nabla_\mu T^{\mu}{}_{x_4} = \partial_{x_4} T^{x_4}{}_{x_4} + \Gamma^{\mu}{}_{\mu x_4} T^{x_4}{}_{x_4} - \sum_{\nu} \Gamma^{\nu}{}_{\nu x_4} T^{\nu}{}_{\nu}.$$

Rule: as before with y replaced by x_4, now with the time derivative of $T^{x_4}{}_{x_4}$ (the flux $T^{y}{}_{x_4}$ along y vanishes for the instantaneous states, ks-theory.json emt.offDiagonal).

$$\Gamma^{\mu}{}_{\mu x_4} = \partial_{x_4} \ln\sqrt{|g|} = 0.$$

Rule: $\sqrt{|g|} = e^{6Hy}$ does not depend on a_4: 3-space grows like e^{3a_4} and the three extra times shrink like e^{-3a_4}, so the proper 7-volume stays the same (check geometry_sqrt_det).

$$\Gamma^{\nu}{}_{\nu x_4} = \tfrac{1}{2}\partial_{x_4} \ln|g_{\nu\nu}| = +a_4' \ (\nu = x_1, x_2, x_3), \quad -a_4' \ (\nu = x_5, x_6, x_7), \quad 0 \ (\nu = x_4, y).$$

Rule: the inflating directions carry e^{2a_4} and the deflating extra times e^{-2a_4}; $\tfrac{1}{2}\partial_{x_4} \ln e^{\pm 2a_4} = \pm a_4'$, with $a_4' = da_4/dx_4$.

$$-\partial_{x_4}\rho - (3a_4'\,p_3 - 3a_4'\,p_t) = 0, \qquad \partial_{x_4}\rho = -3a_4'\,(p_3 - p_t).$$

Rule: $T^{x_4}{}_{x_4} = -\rho$; insert the symbols; then move the bracket to the right side.

$$\frac{\partial \rho}{\partial a_4} = -3\,(p_3 - p_t), \qquad \frac{dE}{da_4} = -3 \cdot 2\,\mathrm{Vol}_7 \int_{-L}^{0} e^{6Hy}\,(p_3 - p_t)\,dy.$$

Rule: along the history $\partial_{x_4} = a_4'\,\partial/\partial a_4$ (chain rule), divide by a_4'; then multiply by $2\,\mathrm{Vol}_7 e^{6Hy}$ and integrate over y, with $E = 2\,\mathrm{Vol}_7 \int e^{6Hy}\rho\,dy = E_{KS}$ (check emt_energy_integral of the solver: relative difference at most 1.6×10^{-15} in all 75 states). This is the **energy-change law** (ks-theory.json, emt.energyChange; PROVED, check emt_x4_component; COMPUTED for all 75 states against differences of the self-consistent energies at neighbouring slices with fixed occupations, check emt_energy_change_dE_da4, worst 1.5×10^{-10}).

How to read it: work. Write the law as $dE = -3\,P_3\,da_4 + 3\,P_t\,da_4$ with the integrated pressures $P_3 = 2\,\mathrm{Vol}_7 \int e^{6Hy} p_3\,dy$ and P_t likewise. When 3-space inflates by da_4, each of its three directions stretches by the factor e^{da_4}, and a gas that pushes outward with the pressure p_3 does work on the expanding space and loses that energy, as a gas in an expanding cylinder pushes a piston. When the three extra times deflate by the same amount, the gas gains $3p_t\,da_4$ per unit volume. Without interaction $p_t = 0$, so the free gas only loses energy, at the rate $3P_3$: this is why E_{KS} falls along the history (Section 15.15). With interaction $p_t = e_{int}$ can have either sign, and the deflation of the extra times can give energy to the gas or take it away; Notebook 15b counts 29 interacting ground states with a positive and 31 with a negative integrated p_t (Out [11]).

Why the gas cannot be the source of the history. In the author's theory the function $a_4(x_4)$ is not free: it must solve the field equations for a_4 (Chapter 12), whose right-hand side is the energy-momentum tensor of the matter. The record `Revision/field_equations_a4/reports/ks-source-conditions.json` lists, under its key conditions, what a source must satisfy:

- (C1) every component of the source is independent of x_0, that is, of y;
- (C2) $p_3 + p_t = 2p_0$ at every point (an algebraic identity of the left-hand side of the a_4 equations, which every source must share);
- (C3) for the linear history $a_4 = AHx_4 + a_0$ used here: $p_3 = p_t = p_0$ and a constant ρ.

The Kohn-Sham gas fails all three. C1: its densities vary strongly with y (Figure 15a.5); the record finds $(\max\rho - \min\rho)/\max|T| \geq 0.0497$ in every state with a nonzero tensor (check ks_profiles_depend_on_x0). C2: $\max|p_3 + p_t - 2p_0|/\max|T|$ lies between 2.09 and 3.99 (check ks_profiles_violate_algebraic_condition), and even the integrated components violate it: $(\int p_3 + \int p_t)/(2\int p_0)$ is 0.339767, 0.259690, 0.239714 for $N = 136$, $\lambda = 0$ at $a_{4,0} = 0, 1, 2$, never close to 1 (check ks_integrals_violate_algebraic_condition). C3: along the history ρ falls (the integral from 80.28 to 12.45 for $N = 136$) and $p_3 \neq p_t$ (check ks_history_is_a_prescribed_background); indeed the energy-change law says that ρ can only stay constant if $p_3 = p_t$. The five free states of $N = 8$ are not covered by these checks: their tensor vanishes identically (only the zero modes are filled), a zero source, for which Einstein gravity has no vacuum solution with $H > 0$ (check ks_zero_source_states_listed). Notebook 15b reproduces these numbers from its own computations (Out [12]). Hence the status: the history $a_4 = AHx_4$ is a **PRESCRIBED BACKGROUND**, and the gas is a **test field** on it, without back-reaction; quantities derived along the history, such as the ratios of integrated pressures below, are not consequences of the coupled field equations. Chapter 17 returns to this question with the full source conditions.

Integrated pressures. The ratio $\int p_3 / \int \rho$ of the free gas is 0.2966, 0.3100, 0.3264 for $N = 136$ at $a_{4,0} = 0, 1, 2$ (Notebook 15b, Out [9]; `Revision/kohn_sham/results/ground/emt-integrals.csv`). It rises toward 1/3, the value for massless particles, because the band levels are nearly linear in the momentum ($\varepsilon \approx c\,k\,e^{-a_{4,0}}$), like massless particles, and become more so as the momenta redshift. These are integrated components on a prescribed background, not an equation of state that an observer in 3-space would measure.

15.17 Example: the energy-momentum profiles (Notebook 15b)

Notebook 15b runs the solver's command `single` for two states, $N = 136$ without interaction at $a_{4,0} = 1$ and $N = 136$ with $+\lambda_2$ at $a_{4,0} = 2$, and checks that their profiles equal the committed ones. It draws the four components as proper densities (Figure 15b.1) and as the densities that are integrated over y (Figure 15b.2), checks the conservation law along y point by point and integrated (Figure 15b.3), solves $N = 136$ at 17 slices and checks the energy-change law at every slice and integrated over the whole history (Figure 15b.4), draws the integrated pressure ratios (Figure 15b.5) and the spreading of the energy toward the tip (Figure 15b.6), shows the interaction terms (Figure 15b.7), and tests the three source conditions on its own numbers. It needs Rust, takes about half a minute, and ends with ALL 18 CHECKS PASSED (notebook 15b).

What to look for: in Figure 15b.1 that the proper densities are huge at the tip and that p_0 changes sign; in Figure 15b.2 that the same quantities times the volume factor sit near the brane; in Figure 15b.3 two curves that lie on top of each other; in Figure 15b.4 short orange lines, computed from the pressures alone, that touch the curve of the energies.

15.18 How to run Notebook 15b

Step 1. What this notebook does and what it needs.

Notebook 15b (Energy-momentum profiles and the conservation law along the hidden direction) is the file `Revision/textbook/notebooks/15b_emt_profiles.ipynb` of the repository Dirac_claude. It runs the Rust Kohn-Sham solver for chosen states of the Kohn-Sham gas of dirac16complex, reads the profiles of the energy density and of the three pressures along the hidden coordinate, checks them against the committed Revision record, verifies the conservation law of the energy-momentum tensor along the hidden direction point by point and integrated, integrates the profiles to the total energy, and checks the energy-change identity dE/da4 = minus three times the integrated difference of the 3-space and extra-time pressures along the deflating history. It also tests, on its own numbers, the three conditions that a source of the equations for a4 must meet, and reproduces the Revision record that shows that the Kohn-Sham states fail them (the history is a prescribed background). Before it runs the solver, the notebook builds it with cargo (a full build of about a minute when the program is missing, a second when it is up to date). The solver writes its output files (about 1 MB) into the folder `Revision/kohn_sham/solver/target/textbook_15b`, which git ignores. It needs a computer with Windows 11, macOS or Linux, an internet connection for the installation, the program Git, and Python 3.12 or newer (the notebooks were built with Python 3.14.5) with these packages at exactly these versions: numpy 2.4.6, sympy 1.14.0, mpmath 1.3.0, matplotlib 3.11.0, jupyterlab 4.4.10, nbformat 5.10.4, nbclient 0.10.2, ipykernel 7.1.0 and nbconvert 7.16.6. The notebook itself imports numpy and matplotlib; the other packages run Jupyter, the program that shows and runs notebooks. It also needs Rust (the program cargo, version 1.91.1 or newer), because

it runs the Rust program revision_ks_solver, which is part of the repository and is built on your computer.

Step 2. Install Git and Python (once per computer).

A terminal is the window in which you type commands: on Windows the app Windows PowerShell (or Terminal), on macOS the app Terminal (it runs the shell zsh), on Linux any terminal (it runs the shell bash). Type every command of this section into a terminal exactly as printed, one line at a time, and press Enter after each line.

Windows: download Git from https://git-scm.com/download/win and install it with the default choices. Download Python from https://www.python.org/downloads/ and run the installer; in its first window tick the box "Add python.exe to PATH" before you click "Install Now".

macOS: download Python from https://www.python.org/downloads/ and run the installer. Then open the app Terminal and run this command, which installs Git and the compiler tools:

macOS (zsh):

```
xcode-select --install
```

Linux (Debian or Ubuntu; other distributions have packages of the same names): run these two commands:

Linux (bash):

```
sudo apt update
sudo apt install git python3 python3-venv
```

Then close the terminal and open a NEW one (a terminal opened before the installation does not know the new programs), and check the version of Python; it must print 3.12 or a higher number:

Windows (PowerShell):

```
py -3 --version
```

macOS (zsh) and Linux (bash):

```
python3 --version
```

If an older Linux prints a lower number (Ubuntu 22.04 has Python 3.10), install Python 3.12 with the following three commands, and in Step 3 type `python3.12` instead of `python3` in the command that creates the environment:

Linux (bash), only when the version is too low:

```
sudo add-apt-repository ppa:deadsnakes/ppa
sudo apt update
sudo apt install python3.12 python3.12-venv
```

Step 3. Get the repository and install the packages (once per computer).

The commands below download the repository (a few hundred megabytes; the folder then needs up to about 1 GB of disk space) into the folder Dirac_claude inside your home folder, create a private Python environment in the folder dirac-book-env inside your home folder (a private environment is a folder with its own copy of Python and of the packages, so that nothing else on your computer is changed), activate it (from then on the commands `python` and `jupyter` typed in this terminal are those of the environment, and the prompt starts with (dirac-book-env)), and install the packages at the pinned versions (this downloads about 90 MB and takes a few minutes; the environment takes about 400 MB of disk space). If you have done this step before, for this or for another notebook, skip it and go to Step 4; to get the newest version of the repository, run `git pull` in the repository folder after Step 4.

Windows (PowerShell):

```
cd $HOME
git clone https://github.com/once-ere/Dirac_claude.git
py -3 -m venv "$HOME\dirac-book-env"
Set-ExecutionPolicy -ExecutionPolicy RemoteSigned -Scope Process -Force
& "$HOME\dirac-book-env\Scripts\Activate.ps1"
python -m pip install --upgrade pip
python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
```

The line with `Set-ExecutionPolicy` allows PowerShell to run the activation script in this one window only; it changes nothing permanently.

macOS (zsh):

```
cd ~
git clone https://github.com/once-ere/Dirac_claude.git
python3 -m venv ~/dirac-book-env
source ~/dirac-book-env/bin/activate
python -m pip install --upgrade pip
python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
```

Linux (bash):

```
cd ~
git clone https://github.com/once-ere/Dirac_claude.git
python3 -m venv ~/dirac-book-env
source ~/dirac-book-env/bin/activate
python -m pip install --upgrade pip
python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
```

Step 4. In every new terminal: activate the environment and go into the repository folder.

Every later step starts in the repository folder with the environment active. Run these lines whenever you open a new terminal (they do no harm if the environment is already active):

Windows (PowerShell):

```
Set-ExecutionPolicy -ExecutionPolicy RemoteSigned -Scope Process -Force
& "$HOME\dirac-book-env\Scripts\Activate.ps1"
cd "$HOME\Dirac_claude"
```

macOS (zsh) and Linux (bash):

```
source ~/dirac-book-env/bin/activate
cd ~/Dirac_claude
```

Step 5. Install Rust and build the Rust program (Rust once per computer, the build once per program).

Windows: download `rustup-init.exe` from https://rustup.rs, run it and accept the default choices; if it reports that the Visual Studio C++ Build Tools are missing, let it install them (or install the workload "Desktop development with C++" from https://visualstudio.microsoft.com/visual-cpp-build-tools/ and run `rustup-init.exe` again). macOS and Linux: run the command below and accept the default choice (on Linux first run `sudo apt install build-essential`, which provides the linker that Rust needs).

macOS (zsh) and Linux (bash):

```
curl --proto "=https" --tlsv1.2 -sSf https://sh.rustup.rs | sh
```

Then close the terminal, open a new one, do Step 4 again, and check the version of cargo; it must print 1.91.1 or a newer version:

Windows, macOS and Linux:

```
cargo --version
```

Build the program with the following command, in the repository folder (the same command on all three systems):

Windows, macOS and Linux:

```
cargo build --release --manifest-path Revision/kohn_sham/solver/Cargo.toml
```

The first build takes about 1 minute; later builds reuse the result and take a few seconds. The program is then the file `Revision/kohn_sham/solver/target/release/revision_ks_solver` (on Windows with the ending `.exe`). The notebook runs the same build command itself before it uses

the program (it takes a second when the program is up to date), so the notebook also works if you skip this build; building here first shows any problem with Rust before the notebook starts.

Step 6. Run the notebook in JupyterLab.

In the repository folder, with the environment active, run these two lines (the first one goes into the folder of the notebooks):

Windows, macOS and Linux:

```
cd Revision/textbook/notebooks
jupyter lab 15b_emt_profiles.ipynb
```

JupyterLab opens in your web browser and shows the notebook (if no browser window opens, copy the address that starts with `http://localhost:8888/lab` from the terminal into the address bar of your browser). The name at the top right of the notebook must read Python 3 (ipykernel). Choose the menu Run > Run All Cells. While a cell runs, the label to its left shows `[*]`; when it has finished, the label shows a number. The notebook has finished when the last code cell shows a number; this takes about 30 seconds on a typical laptop. Scroll to the end and compare the last printed lines with the lines in the step "What the notebook writes and what you must see" below. To keep the results, save the notebook (menu File > Save Notebook). To stop JupyterLab, choose the menu File > Shut Down, or press Ctrl+C twice in the terminal.

Step 7. Or run the notebook without a browser (headless).

In the repository folder, with the environment active, run:

Windows, macOS and Linux:

```
cd Revision/textbook/notebooks
jupyter nbconvert --to notebook --execute --inplace 15b_emt_profiles.ipynb
```

This runs every cell from the top to the bottom and saves the results into the notebook file. A failed check stops it with an error message that contains AssertionError and the name of the check. If the command ends with a line that starts with `[NbConvertApp] Writing` and shows no error, every check passed; open the notebook with `jupyter lab 15b_emt_profiles.ipynb` (in the same folder, without running the cells again) to read the printed lines and see the figures.

Step 8. What the notebook writes and what you must see.

The notebook writes (or overwrites) these files:

- `Revision/textbook/figures/15b.captions.json`
- `Revision/textbook/figures/15b_1_proper_emt.png`
- `Revision/textbook/figures/15b_2_coordinate_emt.png`
- `Revision/textbook/figures/15b_3_y_conservation.png`
- `Revision/textbook/figures/15b_4_energy_slopes.png`

- Revision/textbook/figures/15b_5_integrated_ratios.png
- Revision/textbook/figures/15b_6_energy_spreading.png
- Revision/textbook/figures/15b_7_interaction_terms.png

It changes no other file of the repository except the Rust build folder target next to each Cargo.toml it builds (inside it the notebook keeps the raw output of its program runs in Revision/kohn_sham/solver/target/textbook_15b, which git ignores); running it headless or saving it in JupyterLab also rewrites the notebook file itself. It does not use the internet while it runs. The files it writes are the same files that are stored in the repository (on another computer a figure may differ in a few bytes, which is harmless). To get the stored versions back, run this command in the repository folder (it also undoes every change you made yourself in the folder Revision/textbook):

Windows, macOS and Linux:

```
git checkout -- Revision/textbook
```

Every check of the notebook prints a line that starts with PASS. At the end of the notebook (the output of its last code cell) you must see exactly these lines:

```
PASS every figure file of this notebook exists
ALL 18 CHECKS PASSED (notebook 15b)
```

and the notebook must show 7 figures below the cells that draw them.

Step 9. If something goes wrong.

- "ModuleNotFoundError: No module named ..." in the notebook: JupyterLab was started without the environment. Stop it (menu File > Shut Down), do Step 4, and start it again. If the error remains, another Python installation has registered its own kernel called python3; with the environment active, run the following command and start JupyterLab again:

```
python -m ipykernel install --user --name python3
```

- "FileNotFoundError: The repository folder was not found": the notebook was opened from a copy outside the repository. Open the file Revision/textbook/notebooks/15b_emt_profiles.ipynb inside the folder Dirac_claude.
- "fatal: destination path 'Dirac_claude' already exists" in Step 3: the repository was downloaded before; skip the line with git clone.
- Windows: "running scripts is disabled on this system": run the line with Set-ExecutionPolicy and then the activation line again. "py is not recognized": use python instead of py -3; "python is not recognized": install Python again and tick "Add python.exe to PATH".
- Linux: "ensurepip is not available" when the environment is created: run sudo apt install python3-venv and repeat Step 3.

- "jupyter is not recognized" or "command not found: jupyter": the environment is not active; do Step 4. If the environment is active and the message stays, the programs jupyter-lab and jupyter-nbconvert are not in the folders where the terminal looks for programs (`python -m jupyter` does not help then: it has to find the same programs). Start them through Python itself, in the folder of the notebook: the first command below does what `jupyter lab` does, the second what the headless command does:

```
python -m jupyterlab 15b_emt_profiles.ipynb
python -m nbconvert --execute --inplace 15b_emt_profiles.ipynb
```

- Windows: the headless run prints a RuntimeWarning that mentions the "Proactor event loop" and zmq: this is a message of the package pyzmq, not an error; the run continues normally.
- A red box with "Matplotlib is building the font cache; this may take a moment." in the first run after the installation: this is a message, not an error; the run continues and the message does not come again.
- An AssertionError names a check that failed: choose the menu Kernel > Restart Kernel and Run All Cells; if it fails again, install the packages again with the pip commands of Step 3, because a different package version can change the last digits of a result.
- "cargo is not recognized" or "command not found: cargo" or "cargo was not found": open a new terminal after installing Rust, do Step 4 again, and start JupyterLab from this terminal.
- "linker link.exe not found" (Windows) or "linker cc not found" (Linux): install the C++ Build Tools (Windows) or build-essential (Linux) as described in Step 5 and build again.
- You want the disk space of the solver output back: the folder `Revision/kohn_sham/solver/target/textbook_15b` holds only the raw output of the last run (21 files, about 0.9 MB), which git ignores; delete it at any time, the notebook writes it again.

15.19 Notebook 15b: complete text

This section prints the complete text of the notebook file `Revision/textbook/notebooks/15b_emt_profiles.ipynb`: every cell in order, with the output that the stored, executed notebook holds. A text cell (Jupyter calls it a markdown cell) is printed in a frame after the label Text cell. A code cell is printed after the label In [k], where k is the number that Jupyter gives the cell when it runs it; the text that the cell prints follows after the label Out [k], and every figure that the cell draws follows as a figure with its caption.

Text cell:

```
## 1. What this notebook computes

A Kohn-Sham state of dirac16complex carries energy and momentum. The
**energy-momentum tensor** of the state has four different diagonal components: the
energy density $\rho$ and the pressures $p_3$ (along 3-space), $p_t$ (along the
three extra times) and $p_0$ (along the hidden direction). They depend on the
hidden coordinate $y$. This notebook
```

```
- runs the Rust Kohn-Sham solver for two states and checks that the profiles it
  writes are those of the committed Revision record;
- draws the four components, as proper densities and as the densities that are
  integrated over $y$;
- checks the **conservation law along the hidden direction**,
  $(e^{6Hy} p_0)' = 3H e^{6Hy}(p_3 + p_t)$, point by point and integrated;
- integrates the energy density to the total Kohn-Sham energy;
- solves the state $N = 136$ at 17 slices of the deflating history and checks the
  **energy-change identity**
  $dE/da_4 = -3 \cdot 2\,\mathrm{Vol}_7 \int e^{6Hy}(p_3 - p_t)\,dy$: the energy of
  the gas changes only through the difference between the 3-space pressure and the
  extra-time pressure;
- shows how the interaction adds the same energy density to $p_3$, $p_t$ and $p_0$;
- tests, on its own numbers, the three conditions that a source of the equations
  for $a_4$ must meet, and reproduces the Revision record that shows they fail.

It draws seven figures and takes about half a minute.
```

Text cell:

```
## 2. How to run this notebook

**Step 1. What this notebook does and what it needs.**

Notebook 15b (Energy-momentum profiles and the conservation law along the hidden
direction) is the file ‘Revision/textbook/notebooks/15b_emt_profiles.ipynb‘ of the
repository Dirac_claude. It runs the Rust Kohn-Sham solver for chosen states of the
Kohn-Sham gas of dirac16complex, reads the profiles of the energy density and of the
three pressures along the hidden coordinate, checks them against the committed Revision
record, verifies the conservation law of the energy-momentum tensor along the hidden
direction point by point and integrated, integrates the profiles to the total energy, and
checks the energy-change identity dE/da4 = minus three times the integrated difference of
the 3-space and extra-time pressures along the deflating history. It also tests, on its
own numbers, the three conditions that a source of the equations for a4 must meet, and
reproduces the Revision record that shows that the Kohn-Sham states fail them (the
history is a prescribed background). Before it runs the solver, the notebook builds it
with cargo (a full build of about a minute when the program is missing, a second when it
is up to date). The solver writes its output files (about 1 MB) into the folder
‘Revision/kohn_sham/solver/target/textbook_15b‘, which git ignores. It needs a computer
with Windows 11, macOS or Linux, an internet connection for the installation, the program
Git, and Python 3.12 or newer (the notebooks were built with Python 3.14.5) with these
packages at exactly these versions: numpy 2.4.6, sympy 1.14.0, mpmath 1.3.0, matplotlib
3.11.0, jupyterlab 4.4.10, nbformat 5.10.4, nbclient 0.10.2, ipykernel 7.1.0 and
nbconvert 7.16.6. The notebook itself imports numpy and matplotlib; the other packages
run Jupyter, the program that shows and runs notebooks. It also needs Rust (the program
cargo, version 1.91.1 or newer), because it runs the Rust program revision_ks_solver,
which is part of the repository and is built on your computer.

**Step 2. Install Git and Python (once per computer).**

A terminal is the window in which you type commands: on Windows the app Windows
PowerShell (or Terminal), on macOS the app Terminal (it runs the shell zsh), on Linux any
```

terminal (it runs the shell bash). Type every command of this section into a terminal exactly as printed, one line at a time, and press Enter after each line.

Windows: download Git from https://git-scm.com/download/win and install it with the default choices. Download Python from https://www.python.org/downloads/ and run the installer; in its first window tick the box "Add python.exe to PATH" before you click "Install Now".

macOS: download Python from https://www.python.org/downloads/ and run the installer. Then open the app Terminal and run this command, which installs Git and the compiler tools:

macOS (zsh):

```
xcode-select --install
```

Linux (Debian or Ubuntu; other distributions have packages of the same names): run these two commands:

Linux (bash):

```
sudo apt update
sudo apt install git python3 python3-venv
```

Then close the terminal and open a NEW one (a terminal opened before the installation does not know the new programs), and check the version of Python; it must print 3.12 or a higher number:

Windows (PowerShell):

```
py -3 --version
```

macOS (zsh) and Linux (bash):

```
python3 --version
```

If an older Linux prints a lower number (Ubuntu 22.04 has Python 3.10), install Python 3.12 with the following three commands, and in Step 3 type ‘python3.12‘ instead of ‘python3‘ in the command that creates the environment:

Linux (bash), only when the version is too low:

```
sudo add-apt-repository ppa:deadsnakes/ppa
sudo apt update
sudo apt install python3.12 python3.12-venv
```

Step 3. Get the repository and install the packages (once per computer).

The commands below download the repository (a few hundred megabytes; the folder then needs up to about 1 GB of disk space) into the folder Dirac_claude inside your home folder, create a private Python environment in the folder dirac-book-env inside your home folder (a private environment is a folder with its own copy of Python and of the packages, so that nothing else on your computer is changed), activate it (from then on the commands ‘python‘ and ‘jupyter‘ typed in this terminal are those of the environment, and the prompt starts with (dirac-book-env)), and install the packages at the pinned

versions (this downloads about 90 MB and takes a few minutes; the environment takes about 400 MB of disk space). If you have done this step before, for this or for another notebook, skip it and go to Step 4; to get the newest version of the repository, run ‘git pull‘ in the repository folder after Step 4.

Windows (PowerShell):

```
cd $HOME
git clone https://github.com/once-ere/Dirac_claude.git
py -3 -m venv "$HOME\dirac-book-env"
Set-ExecutionPolicy -ExecutionPolicy RemoteSigned -Scope Process -Force
& "$HOME\dirac-book-env\Scripts\Activate.ps1"
python -m pip install --upgrade pip
python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
```

The line with ‘Set-ExecutionPolicy‘ allows PowerShell to run the activation script in this one window only; it changes nothing permanently.

macOS (zsh):

```
cd ~
git clone https://github.com/once-ere/Dirac_claude.git
python3 -m venv ~/dirac-book-env
source ~/dirac-book-env/bin/activate
python -m pip install --upgrade pip
python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
```

Linux (bash):

```
cd ~
git clone https://github.com/once-ere/Dirac_claude.git
python3 -m venv ~/dirac-book-env
source ~/dirac-book-env/bin/activate
python -m pip install --upgrade pip
python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
```

Step 4. In every new terminal: activate the environment and go into the repository folder.

Every later step starts in the repository folder with the environment active. Run these lines whenever you open a new terminal (they do no harm if the environment is already active):

Windows (PowerShell):

```
Set-ExecutionPolicy -ExecutionPolicy RemoteSigned -Scope Process -Force
& "$HOME\dirac-book-env\Scripts\Activate.ps1"
cd "$HOME\Dirac_claude"
```

macOS (zsh) and Linux (bash):

```
source ~/dirac-book-env/bin/activate
cd ~/Dirac_claude
```

Step 5. Install Rust and build the Rust program (Rust once per computer, the build once per program).

Windows: download ‘rustup-init.exe‘ from https://rustup.rs, run it and accept the default choices; if it reports that the Visual Studio C++ Build Tools are missing, let it install them (or install the workload "Desktop development with C++" from https://visualstudio.microsoft.com/visual-cpp-build-tools/ and run ‘rustup-init.exe‘ again). macOS and Linux: run the command below and accept the default choice (on Linux first run ‘sudo apt install build-essential‘, which provides the linker that Rust needs).

macOS (zsh) and Linux (bash):

```
curl --proto "=https" --tlsv1.2 -sSf https://sh.rustup.rs | sh
```

Then close the terminal, open a new one, do Step 4 again, and check the version of cargo; it must print 1.91.1 or a newer version:

Windows, macOS and Linux:

```
cargo --version
```

Build the program with the following command, in the repository folder (the same command on all three systems):

Windows, macOS and Linux:

```
cargo build --release --manifest-path Revision/kohn_sham/solver/Cargo.toml
```

The first build takes about 1 minute; later builds reuse the result and take a few seconds. The program is then the file ‘Revision/kohn_sham/solver/target/release/revision_ks_solver‘ (on Windows with the ending ‘.exe‘). The notebook runs the same build command itself before it uses the program (it takes a second when the program is up to date), so the notebook also works if you skip this build; building here first shows any problem with Rust before the notebook starts.

Step 6. Run the notebook in JupyterLab.

In the repository folder, with the environment active, run these two lines (the first one goes into the folder of the notebooks):

Windows, macOS and Linux:

```
cd Revision/textbook/notebooks
jupyter lab 15b_emt_profiles.ipynb
```

JupyterLab opens in your web browser and shows the notebook (if no browser window opens, copy the address that starts with ‘http://localhost:8888/lab‘ from the terminal into the address bar of your browser). The name at the top right of the notebook must read Python

3 (ipykernel). Choose the menu Run > Run All Cells. While a cell runs, the label to its left shows ‘[*]‘; when it has finished, the label shows a number. The notebook has finished when the last code cell shows a number; this takes about 30 seconds on a typical laptop. Scroll to the end and compare the last printed lines with the lines in the step "What the notebook writes and what you must see" below. To keep the results, save the notebook (menu File > Save Notebook). To stop JupyterLab, choose the menu File > Shut Down, or press Ctrl+C twice in the terminal.

Step 7. Or run the notebook without a browser (headless).

In the repository folder, with the environment active, run:

Windows, macOS and Linux:

```
cd Revision/textbook/notebooks
jupyter nbconvert --to notebook --execute --inplace 15b_emt_profiles.ipynb
```

This runs every cell from the top to the bottom and saves the results into the notebook file. A failed check stops it with an error message that contains AssertionError and the name of the check. If the command ends with a line that starts with ‘[NbConvertApp] Writing‘ and shows no error, every check passed; open the notebook with ‘jupyter lab 15b_emt_profiles.ipynb‘ (in the same folder, without running the cells again) to read the printed lines and see the figures.

Step 8. What the notebook writes and what you must see.

The notebook writes (or overwrites) these files:

- ‘Revision/textbook/figures/15b.captions.json‘
- ‘Revision/textbook/figures/15b_1_proper_emt.png‘
- ‘Revision/textbook/figures/15b_2_coordinate_emt.png‘
- ‘Revision/textbook/figures/15b_3_y_conservation.png‘
- ‘Revision/textbook/figures/15b_4_energy_slopes.png‘
- ‘Revision/textbook/figures/15b_5_integrated_ratios.png‘
- ‘Revision/textbook/figures/15b_6_energy_spreading.png‘
- ‘Revision/textbook/figures/15b_7_interaction_terms.png‘

It changes no other file of the repository except the Rust build folder ‘target‘ next to each ‘Cargo.toml‘ it builds (inside it the notebook keeps the raw output of its program runs in ‘Revision/kohn_sham/solver/target/textbook_15b‘, which git ignores); running it headless or saving it in JupyterLab also rewrites the notebook file itself. It does not use the internet while it runs. The files it writes are the same files that are stored in the repository (on another computer a figure may differ in a few bytes, which is harmless). To get the stored versions back, run this command in the repository folder (it also undoes every change you made yourself in the folder Revision/textbook):

Windows, macOS and Linux:

```
git checkout -- Revision/textbook
```

Every check of the notebook prints a line that starts with PASS. At the end of the notebook (the output of its last code cell) you must see exactly these lines:

```
PASS every figure file of this notebook exists
```

```
    ALL 18 CHECKS PASSED (notebook 15b)
```

and the notebook must show 7 figures below the cells that draw them.

Step 9. If something goes wrong.

- "ModuleNotFoundError: No module named ..." in the notebook: JupyterLab was started without the environment. Stop it (menu File > Shut Down), do Step 4, and start it again. If the error remains, another Python installation has registered its own kernel called python3; with the environment active, run the following command and start JupyterLab again:

  ```
  python -m ipykernel install --user --name python3
  ```

- "FileNotFoundError: The repository folder was not found": the notebook was opened from a copy outside the repository. Open the file ‘Revision/textbook/notebooks/15b_emt_profiles.ipynb‘ inside the folder Dirac_claude.
- "fatal: destination path ’Dirac_claude’ already exists" in Step 3: the repository was downloaded before; skip the line with ‘git clone‘.
- Windows: "running scripts is disabled on this system": run the line with ‘Set-ExecutionPolicy‘ and then the activation line again. "py is not recognized": use ‘python‘ instead of ‘py -3‘; "python is not recognized": install Python again and tick "Add python.exe to PATH".
- Linux: "ensurepip is not available" when the environment is created: run ‘sudo apt install python3-venv‘ and repeat Step 3.
- "jupyter is not recognized" or "command not found: jupyter": the environment is not active; do Step 4. If the environment is active and the message stays, the programs jupyter-lab and jupyter-nbconvert are not in the folders where the terminal looks for programs (‘python -m jupyter‘ does not help then: it has to find the same programs). Start them through Python itself, in the folder of the notebook: the first command below does what ‘jupyter lab‘ does, the second what the headless command does:

  ```
  python -m jupyterlab 15b_emt_profiles.ipynb
  python -m nbconvert --execute --inplace 15b_emt_profiles.ipynb
  ```

- Windows: the headless run prints a RuntimeWarning that mentions the "Proactor event loop" and zmq: this is a message of the package pyzmq, not an error; the run continues normally.
- A red box with "Matplotlib is building the font cache; this may take a moment." in the first run after the installation: this is a message, not an error; the run continues and the message does not come again.
- An AssertionError names a check that failed: choose the menu Kernel > Restart Kernel and Run All Cells; if it fails again, install the packages again with the pip commands of Step 3, because a different package version can change the last digits of a result.
- "cargo is not recognized" or "command not found: cargo" or "cargo was not found": open a new terminal after installing Rust, do Step 4 again, and start JupyterLab from this terminal.
- "linker link.exe not found" (Windows) or "linker cc not found" (Linux): install the C++ Build Tools (Windows) or build-essential (Linux) as described in Step 5 and build again.
- You want the disk space of the solver output back: the folder ‘Revision/kohn_sham/solver/target/textbook_15b‘ holds only the raw output of the last run (21 files, about 0.9 MB), which git ignores; delete it at any time, the notebook writes it again.

The first code cell below (the set-up cell) repeats these instructions as comments; then it imports the packages, finds the repository folder and defines the helpers ‘save_figure‘ (saves a figure and shows it), ‘check‘ (stops with an AssertionError when a check fails, prints a PASS line when it passes), ‘report‘ (prints a key number as a RESULT line) and ‘all_checks_passed‘ (prints the last line).

In [1]:

```
# HOW TO RUN NOTEBOOK 15b (the complete instructions)
#
# STEP 1. WHAT THIS NOTEBOOK DOES AND WHAT IT NEEDS.
#
# Notebook 15b (Energy-momentum profiles and the conservation law along the hidden
# direction) is the file Revision/textbook/notebooks/15b_emt_profiles.ipynb of the
# repository Dirac_claude. It runs the Rust Kohn-Sham solver for chosen states of the
# Kohn-Sham gas of dirac16complex, reads the profiles of the energy density and of the
# three pressures along the hidden coordinate, checks them against the committed Revision
# record, verifies the conservation law of the energy-momentum tensor along the hidden
# direction point by point and integrated, integrates the profiles to the total energy,
# and checks the energy-change identity dE/da4 = minus three times the integrated
# difference of the 3-space and extra-time pressures along the deflating history. It also
# tests, on its own numbers, the three conditions that a source of the equations for a4
# must meet, and reproduces the Revision record that shows that the Kohn-Sham states fail
# them (the history is a prescribed background). Before it runs the solver, the notebook
# builds it with cargo (a full build of about a minute when the program is missing, a
# second when it is up to date). The solver writes its output files (about 1 MB) into the
# folder Revision/kohn_sham/solver/target/textbook_15b, which git ignores. It needs a
# computer with Windows 11, macOS or Linux, an internet connection for the installation,
# the program Git, and Python 3.12 or newer (the notebooks were built with Python 3.14.5)
# with these packages at exactly these versions: numpy 2.4.6, sympy 1.14.0, mpmath 1.3.0,
# matplotlib 3.11.0, jupyterlab 4.4.10, nbformat 5.10.4, nbclient 0.10.2, ipykernel 7.1.0
# and nbconvert 7.16.6. The notebook itself imports numpy and matplotlib; the other
# packages run Jupyter, the program that shows and runs notebooks. It also needs Rust
# (the program cargo, version 1.91.1 or newer), because it runs the Rust program
# revision_ks_solver, which is part of the repository and is built on your computer.
#
# STEP 2. INSTALL GIT AND PYTHON (ONCE PER COMPUTER).
#
# A terminal is the window in which you type commands: on Windows the app Windows
# PowerShell (or Terminal), on macOS the app Terminal (it runs the shell zsh), on Linux
# any terminal (it runs the shell bash). Type every command of this section into a
# terminal exactly as printed, one line at a time, and press Enter after each line.
#
# Windows: download Git from https://git-scm.com/download/win and install it with the
# default choices. Download Python from https://www.python.org/downloads/ and run the
# installer; in its first window tick the box "Add python.exe to PATH" before you click
# "Install Now".
#
# macOS: download Python from https://www.python.org/downloads/ and run the installer.
# Then open the app Terminal and run this command, which installs Git and the compiler
# tools:
#
```

```
# macOS (zsh):
#     xcode-select --install
#
# Linux (Debian or Ubuntu; other distributions have packages of the same names): run
# these two commands:
#
# Linux (bash):
#     sudo apt update
#     sudo apt install git python3 python3-venv
#
# Then close the terminal and open a NEW one (a terminal opened before the installation
# does not know the new programs), and check the version of Python; it must print 3.12 or
# a higher number:
#
# Windows (PowerShell):
#     py -3 --version
#
# macOS (zsh) and Linux (bash):
#     python3 --version
#
# If an older Linux prints a lower number (Ubuntu 22.04 has Python 3.10), install Python
# 3.12 with the following three commands, and in Step 3 type python3.12 instead of
# python3 in the command that creates the environment:
#
# Linux (bash), only when the version is too low:
#     sudo add-apt-repository ppa:deadsnakes/ppa
#     sudo apt update
#     sudo apt install python3.12 python3.12-venv
#
# STEP 3. GET THE REPOSITORY AND INSTALL THE PACKAGES (ONCE PER COMPUTER).
#
# The commands below download the repository (a few hundred megabytes; the folder then
# needs up to about 1 GB of disk space) into the folder Dirac_claude inside your home
# folder, create a private Python environment in the folder dirac-book-env inside your
# home folder (a private environment is a folder with its own copy of Python and of the
# packages, so that nothing else on your computer is changed), activate it (from then on
# the commands python and jupyter typed in this terminal are those of the environment,
# and the prompt starts with (dirac-book-env)), and install the packages at the pinned
# versions (this downloads about 90 MB and takes a few minutes; the environment takes
# about 400 MB of disk space). If you have done this step before, for this or for another
# notebook, skip it and go to Step 4; to get the newest version of the repository, run
# git pull in the repository folder after Step 4.
#
# Windows (PowerShell):
#     cd $HOME
#     git clone https://github.com/once-ere/Dirac_claude.git
#     py -3 -m venv "$HOME\dirac-book-env"
#     Set-ExecutionPolicy -ExecutionPolicy RemoteSigned -Scope Process -Force
#     & "$HOME\dirac-book-env\Scripts\Activate.ps1"
#     python -m pip install --upgrade pip
#     python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
#     python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
#     python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
#
```

```
# The line with Set-ExecutionPolicy allows PowerShell to run the activation script in
# this one window only; it changes nothing permanently.
#
# macOS (zsh):
#     cd ~
#     git clone https://github.com/once-ere/Dirac_claude.git
#     python3 -m venv ~/dirac-book-env
#     source ~/dirac-book-env/bin/activate
#     python -m pip install --upgrade pip
#     python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
#     python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
#     python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
#
# Linux (bash):
#     cd ~
#     git clone https://github.com/once-ere/Dirac_claude.git
#     python3 -m venv ~/dirac-book-env
#     source ~/dirac-book-env/bin/activate
#     python -m pip install --upgrade pip
#     python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
#     python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
#     python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
#
# STEP 4. IN EVERY NEW TERMINAL: ACTIVATE THE ENVIRONMENT AND GO INTO THE REPOSITORY
# FOLDER.
#
# Every later step starts in the repository folder with the environment active. Run these
# lines whenever you open a new terminal (they do no harm if the environment is already
# active):
#
# Windows (PowerShell):
#     Set-ExecutionPolicy -ExecutionPolicy RemoteSigned -Scope Process -Force
#     & "$HOME\dirac-book-env\Scripts\Activate.ps1"
#     cd "$HOME\Dirac_claude"
#
# macOS (zsh) and Linux (bash):
#     source ~/dirac-book-env/bin/activate
#     cd ~/Dirac_claude
#
# STEP 5. INSTALL RUST AND BUILD THE RUST PROGRAM (RUST ONCE PER COMPUTER, THE BUILD ONCE
# PER PROGRAM).
#
# Windows: download rustup-init.exe from https://rustup.rs, run it and accept the default
# choices; if it reports that the Visual Studio C++ Build Tools are missing, let it
# install them (or install the workload "Desktop development with C++" from
# https://visualstudio.microsoft.com/visual-cpp-build-tools/ and run rustup-init.exe
# again). macOS and Linux: run the command below and accept the default choice (on Linux
# first run sudo apt install build-essential, which provides the linker that Rust needs).
#
# macOS (zsh) and Linux (bash):
#     curl --proto "=https" --tlsv1.2 -sSf https://sh.rustup.rs | sh
#
# Then close the terminal, open a new one, do Step 4 again, and check the version of
# cargo; it must print 1.91.1 or a newer version:
```

```
#
# Windows, macOS and Linux:
#     cargo --version
#
# Build the program with the following command, in the repository folder (the same
# command on all three systems):
#
# Windows, macOS and Linux:
#     cargo build --release --manifest-path Revision/kohn_sham/solver/Cargo.toml
#
# The first build takes about 1 minute; later builds reuse the result and take a few
# seconds. The program is then the file
# Revision/kohn_sham/solver/target/release/revision_ks_solver (on Windows with the ending
# .exe). The notebook runs the same build command itself before it uses the program (it
# takes a second when the program is up to date), so the notebook also works if you skip
# this build; building here first shows any problem with Rust before the notebook starts.
#
# STEP 6. RUN THE NOTEBOOK IN JUPYTERLAB.
#
# In the repository folder, with the environment active, run these two lines (the first
# one goes into the folder of the notebooks):
#
# Windows, macOS and Linux:
#     cd Revision/textbook/notebooks
#     jupyter lab 15b_emt_profiles.ipynb
#
# JupyterLab opens in your web browser and shows the notebook (if no browser window
# opens, copy the address that starts with http://localhost:8888/lab from the terminal
# into the address bar of your browser). The name at the top right of the notebook must
# read Python 3 (ipykernel). Choose the menu Run > Run All Cells. While a cell runs, the
# label to its left shows [*]; when it has finished, the label shows a number. The
# notebook has finished when the last code cell shows a number; this takes about 30
# seconds on a typical laptop. Scroll to the end and compare the last printed lines with
# the lines in the step "What the notebook writes and what you must see" below. To keep
# the results, save the notebook (menu File > Save Notebook). To stop JupyterLab, choose
# the menu File > Shut Down, or press Ctrl+C twice in the terminal.
#
# STEP 7. OR RUN THE NOTEBOOK WITHOUT A BROWSER (HEADLESS).
#
# In the repository folder, with the environment active, run:
#
# Windows, macOS and Linux:
#     cd Revision/textbook/notebooks
#     jupyter nbconvert --to notebook --execute --inplace 15b_emt_profiles.ipynb
#
# This runs every cell from the top to the bottom and saves the results into the notebook
# file. A failed check stops it with an error message that contains AssertionError and
# the name of the check. If the command ends with a line that starts with [NbConvertApp]
# Writing and shows no error, every check passed; open the notebook with jupyter lab
# 15b_emt_profiles.ipynb (in the same folder, without running the cells again) to read
# the printed lines and see the figures.
#
# STEP 8. WHAT THE NOTEBOOK WRITES AND WHAT YOU MUST SEE.
#
```

```
# The notebook writes (or overwrites) these files:
#
# - Revision/textbook/figures/15b.captions.json
# - Revision/textbook/figures/15b_1_proper_emt.png
# - Revision/textbook/figures/15b_2_coordinate_emt.png
# - Revision/textbook/figures/15b_3_y_conservation.png
# - Revision/textbook/figures/15b_4_energy_slopes.png
# - Revision/textbook/figures/15b_5_integrated_ratios.png
# - Revision/textbook/figures/15b_6_energy_spreading.png
# - Revision/textbook/figures/15b_7_interaction_terms.png
#
# It changes no other file of the repository except the Rust build folder target next to
# each Cargo.toml it builds (inside it the notebook keeps the raw output of its program
# runs in Revision/kohn_sham/solver/target/textbook_15b, which git ignores); running it
# headless or saving it in JupyterLab also rewrites the notebook file itself. It does not
# use the internet while it runs. The files it writes are the same files that are stored
# in the repository (on another computer a figure may differ in a few bytes, which is
# harmless). To get the stored versions back, run this command in the repository folder
# (it also undoes every change you made yourself in the folder Revision/textbook):
#
# Windows, macOS and Linux:
#     git checkout -- Revision/textbook
#
# Every check of the notebook prints a line that starts with PASS. At the end of the
# notebook (the output of its last code cell) you must see exactly these lines:
#
#     PASS every figure file of this notebook exists
#     ALL 18 CHECKS PASSED (notebook 15b)
#
# and the notebook must show 7 figures below the cells that draw them.
#
# STEP 9. IF SOMETHING GOES WRONG.
#
# - "ModuleNotFoundError: No module named ..." in the notebook: JupyterLab was started
#   without the environment. Stop it (menu File > Shut Down), do Step 4, and start it
#   again. If the error remains, another Python installation has registered its own
#   kernel called python3; with the environment active, run the following command and
#   start JupyterLab again:
#     python -m ipykernel install --user --name python3
# - "FileNotFoundError: The repository folder was not found": the notebook was opened
#   from a copy outside the repository. Open the file
#   Revision/textbook/notebooks/15b_emt_profiles.ipynb inside the folder Dirac_claude.
# - "fatal: destination path 'Dirac_claude' already exists" in Step 3: the repository was
#   downloaded before; skip the line with git clone.
# - Windows: "running scripts is disabled on this system": run the line with
#   Set-ExecutionPolicy and then the activation line again. "py is not recognized": use
#   python instead of py -3; "python is not recognized": install Python again and tick
#   "Add python.exe to PATH".
# - Linux: "ensurepip is not available" when the environment is created: run sudo apt
#   install python3-venv and repeat Step 3.
# - "jupyter is not recognized" or "command not found: jupyter": the environment is not
#   active; do Step 4. If the environment is active and the message stays, the programs
#   jupyter-lab and jupyter-nbconvert are not in the folders where the terminal looks for
#   programs (python -m jupyter does not help then: it has to find the same programs).
```

```
#   Start them through Python itself, in the folder of the notebook: the first command
#   below does what jupyter lab does, the second what the headless command does:
#     python -m jupyterlab 15b_emt_profiles.ipynb
#     python -m nbconvert --execute --inplace 15b_emt_profiles.ipynb
# - Windows: the headless run prints a RuntimeWarning that mentions the "Proactor event
#   loop" and zmq: this is a message of the package pyzmq, not an error; the run
#   continues normally.
# - A red box with "Matplotlib is building the font cache; this may take a moment." in
#   the first run after the installation: this is a message, not an error; the run
#   continues and the message does not come again.
# - An AssertionError names a check that failed: choose the menu Kernel > Restart Kernel
#   and Run All Cells; if it fails again, install the packages again with the pip
#   commands of Step 3, because a different package version can change the last digits of
#   a result.
# - "cargo is not recognized" or "command not found: cargo" or "cargo was not found":
#   open a new terminal after installing Rust, do Step 4 again, and start JupyterLab from
#   this terminal.
# - "linker link.exe not found" (Windows) or "linker cc not found" (Linux): install the
#   C++ Build Tools (Windows) or build-essential (Linux) as described in Step 5 and build
#   again.
# - You want the disk space of the solver output back: the folder
#   Revision/kohn_sham/solver/target/textbook_15b holds only the raw output of the last
#   run (21 files, about 0.9 MB), which git ignores; delete it at any time, the notebook
#   writes it again.
#

## 3. The words used in this notebook

- **Energy-momentum tensor** $T^\mu{}_\nu$: a table of $8 \times 8$ numbers at each
  point that says how much energy and momentum there is and how it flows. Its
  diagonal holds the **energy density** $\rho = -T^{x_4}{}_{x_4}$ and the
  **pressures** $p_\mu = T^{\mu}{}_{\mu}$ (no sum), the force per area in the
  direction $\mu$ (the sign convention of the Revision record).
- $p_3$: the pressure along each of the three directions of 3-space ($x_1, x_2,
  x_3$); $p_t$: along each extra time ($x_5, x_6, x_7$); $p_0$: along the hidden
  direction.
- **Interaction energy density** $e_{int} = \lambda(\tfrac{15}{32}S^2 -
  \tfrac{1}{32}n^2)$: the energy of the contact interaction per proper 7-volume.
- **Proper density** (per proper 7-volume) and **coordinate density** (per unit of
  $y$ and of the coordinates $x_1 \dots x_7$; it is $e^{6Hy}$ times the proper
  density, because the proper 7-volume of a coordinate box is $e^{6Hy}$ times its
  coordinate volume).
- **Conservation law**: the statement $\nabla_\mu T^\mu{}_\nu = 0$ (the covariant
  divergence vanishes). In flat spacetime it says that energy and momentum are
  neither created nor destroyed, they only flow. In the author's metric, which
  depends on the time $x_4$ through $a_4$, it is a local balance law: the energy is
  not conserved, it changes along the history (sections 4 and 9). The momenta along
  $x_1, x_2, x_3, x_5, x_6, x_7$, coordinates on which the metric does not depend,
  have totals that are constant, but only under ASSUMED boundary conditions
  (Section 20.22 of the book).
- **Finite difference**: an approximation of a derivative from values at nearby
  points; the fourth-order formula
  $f'(y_i) \approx [f_{i-2} - 8 f_{i-1} + 8 f_{i+1} - f_{i+2}]/(12h)$ has an error
  proportional to $h^4$.
- **Symmetric logarithmic axis**: logarithmic for large positive and negative values
  and linear near zero, so that both signs fit on one axis.
- **Tangent**: the straight line that touches a curve at one point; its slope is the
  derivative there.
```

Text cell:

```
## 4. The physical and mathematical situation
```

Geometry. In the hidden coordinate y (tip $y = -L = -3$, brane $y = 0$) the author's metric reads (Revision record Revision/kohn_sham/ks-theory.json)

$$ds^2 = e^{2Hy}\left[e^{2a_4}(dx_1^2 + dx_2^2 + dx_3^2) - e^{-2a_4}(dx_5^2 + dx_6^2
+ dx_7^2)\right] - dx_4^2 + dy^2 .$$

3-space (x_1, x_2, x_3) inflates with e^{a_4} while the three extra times (x_5, x_6, x_7) deflate with e^{-a_4}; the proper 7-volume factor is $\sqrt{|g|} = e^{6Hy}$, the same at every slice $a_{4,0}$.

The tensor of a Kohn-Sham state (ks-theory.json, emt; sums over the occupied levels with the weights $w g f$, $w = 1/2$; n_o, s_o, t_o are the number, scalar and current densities of one orbital):

$$\rho = \sum w g f\,\varepsilon\,n_o - e_{int}, \qquad
p_3 = \sum w g f\,\tfrac{\kappa |k|}{3}\,t_o + e_{int}, \qquad p_t = e_{int},$$
$$p_0 = \sum w g f\left[(\varepsilon - v)\,n_o - M s_o - \kappa|k|\,t_o\right]
+ e_{int} .$$

The extra-time pressure contains no kinetic part: the states belong to the *good sector*, which has no momentum along the extra times.

Conservation along y. For a tensor that is diagonal and depends only on y, the y component of $\nabla_\mu T^\mu{}_\nu = 0$ is

$$\partial_y T^y{}_y + \Gamma^\mu{}_{\mu y} T^y{}_y
- \sum_\nu \Gamma^\nu{}_{\nu y} T^\nu{}_\nu = 0$$

(the index ν runs over the eight directions; the letter λ is kept for the coupling). Line by line:
$\Gamma^\mu{}_{\mu y} = \partial_y \ln\sqrt{|g|} = 6H$ (the derivative of $\ln e^{6Hy}$); $\Gamma^\nu{}_{\nu y} = \tfrac12 g^{\nu\nu}\partial_y g_{\nu\nu} = H$ for each of the six warped directions $x_1, x_2, x_3, x_5, x_6, x_7$ (their $g_{\nu\nu}$ contains the factor e^{2Hy}, and half the derivative of $\ln e^{2Hy}$ is H) and 0 for x_4 and y; the six warped terms are $3H p_3$ (3-space) and $3H p_t$ (extra times); so

$$p_0' + 6H p_0 - 3H p_3 - 3H p_t = 0, \quad\text{that is}\quad
(e^{6Hy} p_0)' = 3H\,e^{6Hy}(p_3 + p_t),$$

because $(e^{6Hy}p_0)' = e^{6Hy}(p_0' + 6Hp_0)$ (product and chain rule). Integrated from tip to brane: $[e^{6Hy}p_0]_{-L}^{0} = 3H \int_{-L}^{0} e^{6Hy}(p_3 + p_t)\,dy$.

Energy change along the history. The x_4 component of the same law reads $\partial_{x_4} T^{x_4}{}_{x_4} + \Gamma^\mu{}_{\mu x_4} T^{x_4}{}_{x_4} - \sum_\nu \Gamma^\nu{}_{\nu x_4} T^\nu{}_\nu = 0$. Line by line:
$T^{x_4}{}_{x_4} = -\rho$ (the sign convention); $\Gamma^\mu{}_{\mu x_4} = \partial_{x_4}\ln\sqrt{|g|} = 3a_4' - 3a_4' = 0$ (3-space grows like e^{3a_4}, the extra times shrink like e^{-3a_4}, so the 7-volume is constant); $\Gamma^\nu{}_{\nu x_4} = \tfrac12 g^{\nu\nu}\partial_{x_4} g_{\nu\nu} = +a_4'$ for the three inflating directions ($g_{\nu\nu} \propto e^{2a_4}$) and $-a_4'$ for the three deflating extra times ($g_{\nu\nu} \propto e^{-2a_4}$), 0 for x_4 and y. So $-\partial_{x_4}\rho - (3a_4' p_3 - 3a_4' p_t) = 0$, that is $\partial_{x_4}\rho = -3 a_4'(p_3 - p_t)$. Along the history a_4 grows with x_4,

```
so $\partial_{x_4} = a_4'\,\partial/\partial a_4$ (chain rule) and
$\partial\rho/\partial a_4 = -3(p_3 - p_t)$. Multiplying by $2\,\mathrm{Vol}_7
e^{6Hy}$ and integrating over $y$ gives, for the total energy
$E = 2\,\mathrm{Vol}_7\int e^{6Hy}\rho\,dy$ of the doubled system of states that
follow the history adiabatically (the solver checks it with the Hellmann-Feynman
theorem),

$$\frac{dE}{da_4} = -3 \cdot 2\,\mathrm{Vol}_7 \int_{-L}^{0} e^{6Hy}(p_3 - p_t)\,dy .$$

Read as work: when 3-space inflates by $da_4$, the gas loses the energy
$3\,p_3\,da_4$ per unit proper volume (the work done by its 3-space pressure), and
when the three extra times deflate by the same amount it gains $3\,p_t\,da_4$.
Here $p_t = e_{int}$ is the interaction energy density alone: it is zero without
interaction and can have either sign (positive or negative integrals both occur in
the record), so the deflation can return energy to the gas or take more away.

**Status.** The tensor is COMPUTED by the solver; the two identities are exact and
are checked here numerically. The history $a_4 = A H x_4$ is a PRESCRIBED
BACKGROUND: the Kohn-Sham tensor depends on $y$ (hence on $x_0$) and has
$p_3 + p_t \ne 2 p_0$, so it is not an admissible source of the equations for $a_4$
(Revision record Revision/field_equations_a4/reports/ks-source-conditions.json).
Units: $H = m = 1$, $L = 3$, $\mathrm{Vol}_7 = (2\pi/0.25)^3$.
```

```
## 5. Building the solver and producing two profiles

The next cell builds the solver (‘rust_program‘, about a second when it is up to
date) and defines a helper ‘solve_state‘ that runs the subcommand ‘single‘ for one
state: ‘--m‘, ‘--lambda‘, ‘--a4‘, ‘--N‘ give the mass, coupling, slice and particle
number, ‘--out‘ names the JSON file of the results and ‘--profiles‘ the CSV file of
the profiles. The files go into the folder ‘textbook_15b‘ inside the Rust build
folder ‘target‘, which git ignores.
```

In [2]:

```
import csv  # reads the tables (CSV files)
import math  # exp and pi for single numbers

import numpy as np  # arrays of numbers

program = rust_program("Revision/kohn_sham/solver/Cargo.toml", "revision_ks_solver")

```
The next cell reads the two new profile files and the corresponding committed files
of the record (‘ground/profiles/N136_lam0_a10.csv‘ and ‘N136_lamp2_a20.csv‘) and
compares every column. The largest difference is measured relative to the largest
value of each column; the tolerance $10^{-9}$ is far below the accuracy of the
profiles themselves ($10^{-6}$, the tolerance of the record’s refined comparison).
Whether the files are byte-identical is printed as a RESULT line.
```

## 6. The four components as proper densities

The next cell draws $\rho$, $p_3$, $p_t$ and $p_0$ of the state $N = 136$,
$\lambda = 0$, $a_{4,0} = 1$ against $y$. The values span six orders of magnitude and
$p_0$ changes sign, so the vertical axis is symmetric logarithmic (linear between
$-10^{-3}$ and $10^{-3}$). Without interaction $p_t = e_{int} = 0$ exactly; the
check confirms it.
```

In [4]:

```

```
## 7. What is integrated: the coordinate densities

Multiplying by $2\,\mathrm{Vol}_7\, e^{6Hy}$ turns a proper density into the amount
per unit of $y$ in the whole box of the doubled system. The next cell draws these
densities (now on a linear axis) and integrates them with Simpson's rule on the 151
points: the integral of the energy density must be the Kohn-Sham energy $E_{KS}$ of
the solver's JSON record (and of the committed table 'ground/summary.csv'), and the
integrals of the pressures must agree with the committed table
```

‘ground/emt-integrals.csv‘. The solver integrates on a finer grid (1801 points), so
the comparison allows a relative difference of 10^{-6}.

## 8. The conservation law along the hidden direction

The next cell computes the left side $(e^{6Hy}p_0)'$ by the fourth-order finite
difference (one-sided fourth-order formulas at the two ends, as in the solver) and
the right side $3H e^{6Hy}(p_3 + p_t)$, draws both, and draws their difference
divided by the largest of the two sides. It also compares the jump
$[e^{6Hy}p_0]_{-3}^{0}$ with the integral of the right side. The solver checked the
same law on its fine grid (record checks ‘emt_y_conservation_pointwise‘ and
‘emt_y_conservation_integrated‘); on the 151 points of the profile the finite
difference is less accurate, so the tolerances here are $10^{-4}$ (point by point)
and $10^{-6}$ (integrated).
```

## 9. The energy along the history and its slope

The next cell solves the state $N = 136$ without interaction at 17 slices,
$a_{4,0} = 0, 0.125, 0.25, \dots, 2$ (about a third of a second each), and reads
from each JSON record the energy $E_{KS}$ and the integrals
$2\,\mathrm{Vol}_7\int e^{6Hy}(\cdot)\,dy$ of $\rho$, $p_3$, $p_t$, $p_0$ that the
solver computed on its fine grid. From them it forms the slope
$-3(\int p_3 - \int p_t)$ of the energy-change identity. At the five slices of the
canonical matrix the energies and integrals must equal the committed tables, and
the slopes must equal the derivative $dE/da_4$ that the solver obtained by
finite differences between neighbouring slices (column ‘dE_da4_finite_difference‘
of ‘adiabatic/adiabaticity.csv‘).
```

## 10. The integrated pressures along the history

The next cell divides the integrated pressures by the integrated energy density.
These ratios are the integrated components only: what a 3-space observer would call
an equation of state is not computed here (it needs the averaging over the hidden
direction and the extra times, which is the subject of the Revision dark-sector
work), and the history is a prescribed background. The figure shows
$\int p_3/\int\rho$ and $\int p_0/\int\rho$ for $N = 136$ at the 17 slices (lines)
and for $N = 136$ and $N = 688$ at the five slices of the record (markers). The check
compares the ratios of $N = 136$ at the five slices with the committed table.
```

## 11. Where the energy sits along the history

The next cell reads the committed profiles of $N = 136$, $\lambda = 0$ at the five
slices and draws the coordinate energy density divided by the total energy,
$2\,\mathrm{Vol}_7 e^{6Hy}\rho(y)/E_{KS}$, whose area is 1. As the brane band
redshifts, its orbitals reach further from the brane toward the tip. The check
measures this with the mean position $\langle y \rangle = \int y \cdot (\text{this
density})\,dy$, which must decrease from slice to slice.
```

## 12. The interaction terms

With interaction the energy density $e_{int}$ enters every component: it is
```

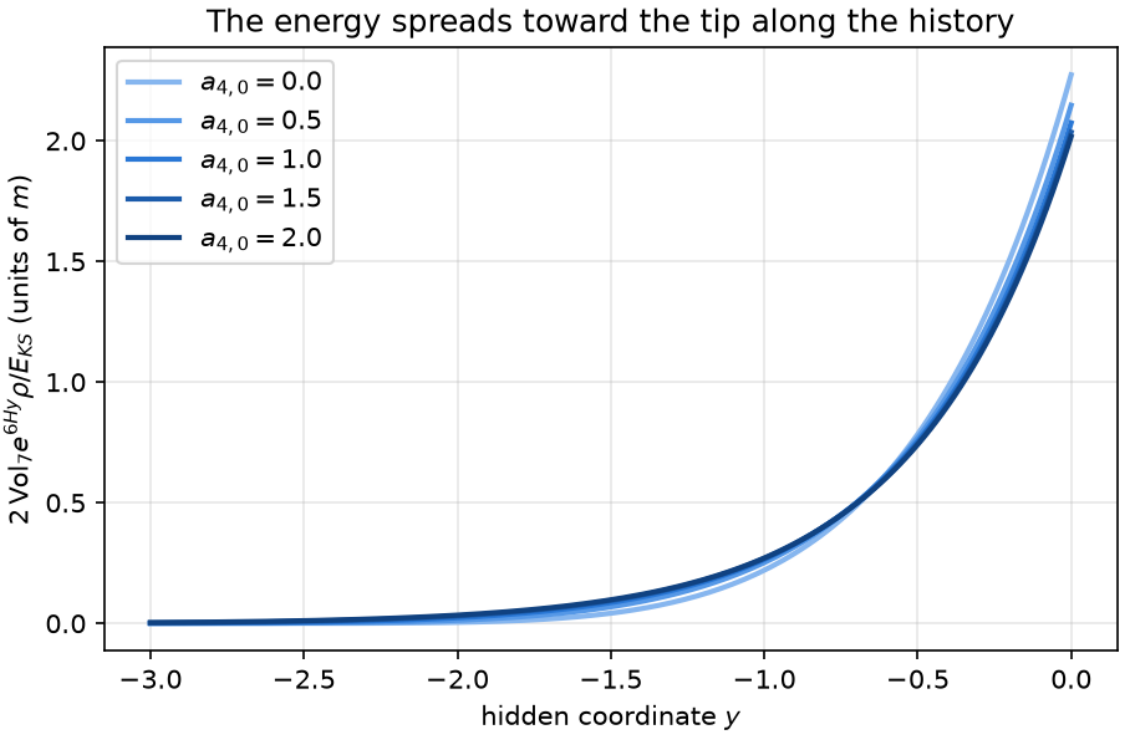

Figure 424: The energy per unit y divided by the total energy, $2\,\mathrm{Vol}_7 e^{6Hy}\rho(y)/E_{KS}$ (vertical axis, area 1), of $N = 136$ without interaction at the five slices $a_{4,0} = 0$ to 2 (light to dark blue), against y (horizontal axis). The energy is concentrated near the brane, and its distribution moves toward the tip as the history proceeds. (Notebook 15b, figure 6.)

```
subtracted in $\rho$ and added to $p_3$, $p_0$ and, alone, forms $p_t$. The next
cell uses the strongly interacting state $N = 136$, $+\lambda_2$, $a_{4,0} = 2$: it
draws $e_{int}$ and its two parts $\tfrac{15}{32}\lambda S^2$ and
$-\tfrac{1}{32}\lambda n^2$ (computed here from the profile columns $S$ and $n$),
checks that the column $e_{int}$ of the profile is this sum and that $p_t = e_{int}$
exactly, and checks the conservation law for this state too (where $p_t \ne 0$).
Finally it counts, among the 60 interacting ground states of the committed table
‘ground/emt-integrals.csv‘, how many have a positive and how many a negative
integrated extra-time pressure $2\,\mathrm{Vol}_7\int e^{6Hy}p_t\,dy$: both signs
occur, so the deflation of the extra times can give energy to the gas or take
energy from it.
```

## 13. Why this tensor cannot drive the history

The field equations for $a_4$ (the Einstein-Lovelock equations of the author's
metric) accept a source only under three conditions (Revision record
Revision/field_equations_a4/reports/ks-source-conditions.json, key `conditions`):

- (C1) every component of the source is independent of $x_0$, that is, of $y$;
- (C2) $p_3 + p_t = 2 p_0$ at every point;
- (C3) for the linear history $a_4 = AHx_4 + a_0$ used here: $p_3 = p_t = p_0$
  and a constant $\rho$.

The next cell tests the three conditions on this notebook's own numbers: the
profile of $N = 136$, $\lambda = 0$, $a_{4,0} = 1$ for C1 and C2 point by point,
and the 17 slices of the history for C2 after the integration over $y$ and for C3.
It prints the profile at $y = -3, -1.5, 0$ and checks these values and the
integrated ratios $(\int p_3 + \int p_t)/(2\int p_0)$ at $a_{4,0} = 0, 1, 2$
against the numbers printed in the record's checks (6 significant digits). All
three conditions fail, as the record says: the Kohn-Sham gas is a test field on a
PRESCRIBED BACKGROUND, not a source that would produce the deflating history.
```

Text cell:

```
## 15. What this notebook showed

- The solver's profiles of the energy density and the three pressures are
  reproduced on this computer, and their integrals give the Kohn-Sham energy
  (COMPUTED).
- The conservation law along the hidden direction,
  $(e^{6Hy}p_0)' = 3H e^{6Hy}(p_3 + p_t)$, holds point by point and integrated, with
  and without interaction (an exact identity, checked numerically).
- Along the deflating history the energy of the gas changes exactly by the work of
  the pressure difference, $dE/da_4 = -3 \cdot 2\,\mathrm{Vol}_7\int e^{6Hy}(p_3 -
  p_t)\,dy$: the 3-space pressure takes energy from the gas as 3-space inflates,
  and the extra-time pressure, which is only the interaction energy density (zero
  without interaction, of either sign with it), adds or removes a small amount as
  the extra times deflate.
- The integrated ratio $\int p_3/\int\rho$ rises toward $1/3$ as the momenta
  redshift; the energy moves toward the tip.
- The history is PRESCRIBED: these components are not an admissible source of the
  equations for $a_4$ (they depend on $y$, $p_3 + p_t \ne 2p_0$, and along the
  history $\rho$ changes and $p_3 \ne p_t$; checked here on the notebook's own
  numbers), and no equation of state seen by an observer is claimed here.
```

15.20 Line-by-line walk-through of Notebook 15b

The notebook has 13 code cells, In [1] to In [13]. As before, docstrings are left out of the quotations and long caption strings are shortened; the complete cells are printed in Section 15.19.

In [1], the set-up cell. It is the set-up cell of Notebook 15a (Section 15.14, which explains the two Rust lines and the function `rust_program`; the rest is explained in Section 15.9), with the run instructions of this notebook (Section 15.18) in its comments and `NOTEBOOK_ID = "15b"`.

In [2], the solver and two profiles.

```
import csv  # reads the tables (CSV files)
import math  # exp and pi for single numbers

import numpy as np  # arrays of numbers
```

```
program = rust_program("Revision/kohn_sham/solver/Cargo.toml", "revision_ks_solver")
RUN_FOLDER = REPO / "Revision/kohn_sham/solver/target/textbook_15b"  # ignored by git
RUN_FOLDER.mkdir(parents=True, exist_ok=True)
```

The imports, the solver built (about a second when it is up to date), and the folder `textbook_15b` inside the solver's build folder, which git ignores, for the files of this notebook's runs.

```
PALETTE = ["#2a78d6", "#eb6834", "#1baf7a", "#eda100", "#e87ba4", "#008300",
           "#4a3aa7", "#e34948"]  # the colours of the figures, in a fixed order
SLICE_SHADES = ["#86b6ef", "#5598e7", "#2a78d6", "#1c5cab", "#104281"]  # light->dark
VOL7 = (2.0 * math.pi / 0.25) ** 3  # proper 7-volume per unit e^{6Hy}
H = 1.0
```

The colours (as in Notebook 15a), $\mathrm{Vol}_7 = 15875.2137$ and $H = 1$.

```
def solve_state(name, n, lam, a4, profiles=False):
    out = RUN_FOLDER / f"{name}.json"
    command = [str(program), "single", "--root", str(REPO), "--m", "1",
               "--lambda", repr(lam), "--a4", repr(a4), "--N", repr(float(n)),
               "--out", str(out)]
    if profiles:
        command += ["--profiles", str(RUN_FOLDER / f"{name}.csv")]
    done = subprocess.run(command, capture_output=True, text=True)
    if done.returncode != 0 or done.stdout.strip().split("\n")[-1] != "SUCCESS":
        raise RuntimeError(f"the solver failed for {name}: {done.stderr[-500:]}")
    return json.loads(out.read_text(encoding="utf-8"))
```

`solve_state` runs the solver's command `single` for one state and returns its JSON record as a dictionary. The command list holds the program, the word `single`, the repository, the mass 1, the coupling, the slice and the particle number; `repr(x)` writes a number with all the digits needed to read it back exactly. If profiles are wanted, the option that names a CSV file for them is appended (`+=` extends the list). If the program fails, or its last printed line is not SUCCESS, the notebook stops with the end of its error message.

```
params = json.loads(repository_file("Revision/kohn_sham/results/parameters.json")
                    .read_text(encoding="utf-8"))
LAMBDA2_136 = {int(c["N"]): c for c in params["couplingCalibration"]["values"]}[136][
    "lambda2"]  # the coupling lambda_2 of N = 136
free_state = solve_state("N136_lam0_a10", 136, 0.0, 1.0, profiles=True)
strong_state = solve_state("N136_lamp2_a20", 136, LAMBDA2_136, 2.0, profiles=True)
say(f"solved N136_lam0_a10 ({free_state['iterations']} iteration) and N136_lamp2_a20 "
    f"({strong_state['iterations']} iterations, lambda = {LAMBDA2_136})")
```

The coupling $\lambda_2 = 0.002789$ of $N = 136$ is read from the record. Two states are solved with profiles: the free state at $a_{4,0} = 1$ and the strongly interacting state at $a_{4,0} = 2$. Out [2] reports 1 iteration for the free state (without interaction one iteration is exact) and 17 for the other.

In [3], comparison with the committed profiles.

```
RECORD_PROFILES = "Revision/kohn_sham/results/ground/profiles"

def read_profile(path):
    data = np.genfromtxt(path, delimiter=",", names=True)
    return {name: data[name] for name in data.dtype.names}
```

`read_profile` is the function of Notebook 15a (Section 15.14, In [12]), here with a path as its argument.

```
worst = 0.0
identical = []
for name in ("N136_lam0_a10", "N136_lamp2_a20"):
    new = read_profile(RUN_FOLDER / f"{name}.csv")
    old = read_profile(repository_file(f"{RECORD_PROFILES}/{name}.csv"))
    for column in old:
        scale = max(float(np.max(np.abs(old[column]))), 1e-300)
        worst = max(worst, float(np.max(np.abs(new[column] - old[column]))) / scale)
    identical.append((RUN_FOLDER / f"{name}.csv").read_bytes()
                     == repository_file(f"{RECORD_PROFILES}/{name}.csv").read_bytes())
```

For both states and every column the largest difference between the new and the committed profile is divided by the largest value of the column (or by 10^{-300}, so that a column of zeros does not cause a division by zero), and the largest such ratio is kept. The byte identity of each pair of files is recorded in the list `identical`.

```
say("columns: " + ", ".join(old))
report("largest relative difference to the record", f"{worst:.1e}")
report("profile files byte-identical to the record", identical)
check(worst < 1e-9, "the new profiles equal the committed profiles within 1e-9",
      record=f"{RECORD_PROFILES}/N136_lam0_a10.csv and N136_lamp2_a20.csv")
```

Out [3] lists the twelve columns (y, n, S, Q, M, v, w_Q, e_{int}, ρ, p_3, p_t, p_0; Q and w_Q belong to the exact-Fock variant), a difference of 0.0, the files byte-identical, and PASS.

In [4], the proper densities.

```
prof = read_profile(RUN_FOLDER / "N136_lam0_a10.csv")
y = prof["y"]
step = float(y[1] - y[0])  # 0.02
COMPONENTS = [("rho", "$\\rho$"), ("p3", "$p_3$"), ("p_t", "$p_t$"), ("p0", "$p_0$")]
fig, ax = plt.subplots()
for colour, (column, label) in zip(PALETTE, COMPONENTS):
    ax.plot(y, prof[column], color=colour, lw=2.0, label=label)
ax.set_yscale("symlog", linthresh=1e-3)
```

The free profile is read; `y` are its 151 coordinates with the spacing `step` $= 0.02$. `COMPONENTS` pairs the column names with their labels, and the four components are drawn on a symmetric logarithmic axis (linear between -10^{-3} and 10^{-3}), because they span six powers of ten and p_0 changes sign.

```
ax.set_xlabel("hidden coordinate $y$ (tip at $-3$, brane at $0$)")
ax.set_ylabel("proper density (units of $m^8$)")
ax.set_title("Energy density and pressures, $N = 136$, $\\lambda = 0$, $a_{4,0} = 1$")
ax.legend()
save_figure(fig, "proper_emt",
            "The energy density $\\rho$ and the pressures $p_3$, $p_t$, $p_0$ of the "
...)
report("p_t without interaction: largest |p_t|", float(np.max(np.abs(prof["p_t"]))))
check(float(np.max(np.abs(prof["p_t"]))) == 0.0, "p_t = e_int = 0 when lambda = 0")
```

The labels (a proper energy density has the unit m^8 in eight dimensions), Figure 15b.1, and the check that p_t is exactly zero without interaction (Out [4]). In the figure all components are largest at the tip, and p_0 is negative near the tip and changes sign near $y = -2.45$.

In [5], the coordinate densities and their integrals.

```
def simpson(values, h):
    weights = np.full(len(values), 2.0)
    weights[1::2] = 4.0
    weights[0] = weights[-1] = 1.0
    return h / 3.0 * float(np.sum(weights * values))

def read_rows(relative):
    with open(repository_file(relative), newline="", encoding="utf-8") as handle:
        return {row["id"]: row for row in csv.DictReader(handle)}
```

`simpson` is Simpson's rule (Section 15.14, In [12]); `read_rows` reads a committed table of the record and files its rows by state name.

```
EMT_TABLE = "Revision/kohn_sham/results/ground/emt-integrals.csv"
emt_rows = read_rows(EMT_TABLE)
summary_rows = read_rows("Revision/kohn_sham/results/ground/summary.csv")
weight = 2.0 * VOL7 * np.exp(6.0 * H * y)  # 2 Vol_7 e^{6Hy}
fig, ax = plt.subplots()
integrals = {}
for colour, (column, label) in zip(PALETTE, COMPONENTS):
    ax.plot(y, weight * prof[column], color=colour, lw=2.0, label=label)
    integrals[column] = simpson(weight * prof[column], step)
```

The record's table of the integrals $2\,\mathrm{Vol}_7 \int e^{6Hy}(\cdot)\,dy$ and its summary table are read. `weight` is $2\,\mathrm{Vol}_7 e^{6Hy}$, which turns a proper density into the amount per unit y in the doubled box. Each component times the weight is drawn and integrated.

```
ax.axhline(0.0, color="0.4", lw=0.8)
ax.set_xlabel("hidden coordinate $y$")
ax.set_ylabel("$2\\,\\mathrm{Vol}_7\\, e^{6Hy} \\times$ component (units of $m$)")
ax.set_title("The integrands: energy and pressures per unit $y$")
ax.legend()
save_figure(fig, "coordinate_emt",
```

```
            "The energy density and the pressures of the state $N = 136$, "
...)
row = emt_rows["N136_lam0_a10"]
rel = lambda a, b: abs(a - b) / max(abs(b), 1e-300)
worst_int = max(rel(integrals[c], float(row[f"int_{c}"])) for c in ("rho", "p3", "p0"))
```

A zero line, labels, Figure 15b.2. `rel` is the relative difference of two numbers, and `worst_int` the largest relative difference between this notebook's integrals of ρ, p_3, p_0 and the record's columns `int_rho`, `int_p3`, `int_p0`.

```
report("E_KS from the profile / from the solver",
       f"{integrals['rho']:.8f} / {free_state['E_KS']:.8f}")
report("largest relative difference of the integrals to the record", f"{worst_int:.1e}")
check(rel(free_state["E_KS"], float(summary_rows["N136_lam0_a10"]["E_KS"])) < 1e-12,
      "the solver's E_KS equals the record",
      record="Revision/kohn_sham/results/ground/summary.csv, N136_lam0_a10")
check(rel(integrals["rho"], free_state["E_KS"]) < 1e-6 and worst_int < 1e-6,
      "Simpson's rule on the profile gives E_KS and the recorded integrals",
      record=f"{EMT_TABLE}, columns int_rho, int_p3, int_p0")
```

Out [5]: the integral of the energy density over the 151 profile points is 32.38411614 against the solver's $E_{KS} = 32.38411569$ (a relative difference of 1.4×10^{-8}, the error of Simpson's rule on the coarse profile grid); both checks pass. In Figure 15b.2 the energy and the pressures sit near the brane.

In [6], the conservation law along y.

```
def derivative4(f, h):
    d = np.zeros(len(f))
    d[2:-2] = (f[:-4] - 8.0 * f[1:-3] + 8.0 * f[3:-1] - f[4:]) / (12.0 * h)
    d[0] = (-25 * f[0] + 48 * f[1] - 36 * f[2] + 16 * f[3] - 3 * f[4]) / (12.0 * h)
    d[1] = (-3 * f[0] - 10 * f[1] + 18 * f[2] - 6 * f[3] + f[4]) / (12.0 * h)
    d[-1] = (25 * f[-1] - 48 * f[-2] + 36 * f[-3] - 16 * f[-4] + 3 * f[-5]) / (12.0 * h)
    d[-2] = (3 * f[-1] + 10 * f[-2] - 18 * f[-3] + 6 * f[-4] - f[-5]) / (12.0 * h)
    return d
```

`derivative4` computes the derivative of equally spaced values with error proportional to h^4. At the inner points it uses $f'(y_i) \approx [f_{i-2} - 8f_{i-1} + 8f_{i+1} - f_{i+2}]/(12h)$; `f[:-4]`, `f[1:-3]`, `f[3:-1]` and `f[4:]` are the arrays shifted so that position i of each holds f_{i-2}, f_{i-1}, f_{i+1}, f_{i+2} for the points 2 to 148. At the two first and two last points, where two neighbours on one side are missing, one-sided formulas of the same order use five points on one side. (Each of these formulas is the derivative of the polynomial of degree 4 through the five points.)

```
def conservation(p):
    e6 = np.exp(6.0 * H * p["y"])
    left = derivative4(e6 * p["p0"], step)
    right = 3.0 * H * e6 * (p["p3"] + p["p_t"])
    scale = max(float(np.max(np.abs(left))), float(np.max(np.abs(right))))
    jump = e6[-1] * p["p0"][-1] - e6[0] * p["p0"][0]
    integral = simpson(right, step)
    return left, right, np.abs(left - right) / scale, abs(jump - integral) / abs(jump)
```

`conservation` returns, for a profile, the left side $(e^{6Hy}p_0)'$, the right side $3H\,e^{6Hy}(p_3+p_t)$, their difference at every point divided by the largest value of the two sides, and the integrated residual: the jump $[e^{6Hy}p_0]_{-3}^{0}$ compared with the integral of the right side, relative to the jump.

```
left, right, residual, integrated = conservation(prof)
fig, (ax1, ax2) = plt.subplots(1, 2, figsize=(10.0, 4.0), layout="constrained")
ax1.plot(y, left, color=PALETTE[0], lw=3.0, label="$(e^{6Hy}p_0)'$")
ax1.plot(y, right, color=PALETTE[1], lw=1.5, ls="--",
         label="$3H\\,e^{6Hy}(p_3 + p_t)$")
ax1.set_xlabel("hidden coordinate $y$")
ax1.set_ylabel("units of $m^9$")
ax1.set_title("The two sides of the law")
ax1.legend()
```

The left panel draws both sides, the left side as a thick line and the right side dashed on top of it.

```
ax2.semilogy(y, np.maximum(residual, 1e-16), color=PALETTE[2], lw=1.5)
ax2.axhline(1e-4, color="0.4", ls=":", lw=1.2, label="tolerance $10^{-4}$")
ax2.set_xlabel("hidden coordinate $y$")
ax2.set_ylabel("|left - right| / largest value")
ax2.set_title("Relative residual on the 151 points")
ax2.legend()
save_figure(fig, "y_conservation",
            "Left: the two sides of the conservation law along the hidden "
...)
report("largest pointwise residual / integrated residual",
       f"{float(np.max(residual)):.1e} / {integrated:.1e}")
check(float(np.max(residual)) < 1e-4 and integrated < 1e-6,
      "(e^{6Hy} p0)' = 3H e^{6Hy} (p3 + p_t) holds for N136_lam0_a10",
      record="Revision/kohn_sham/reports/ks-rust-solver.json, checks "
             "emt_y_conservation_pointwise and emt_y_conservation_integrated")
```

The right panel draws the relative residual on a logarithmic axis (`np.maximum(residual, 1e-16)` raises exact zeros to 10^{-16}, because a logarithmic axis cannot show 0), with the tolerance 10^{-4} as a dotted line; then Figure 15b.3. Out [6]: the largest pointwise residual is 2.5×10^{-8} and the integrated one 6.1×10^{-10}, far below the tolerances; the law holds.

In [7], the energy at 17 slices and its slope.

```
DENSE = [i / 8.0 for i in range(17)]  # the slices 0, 0.125, ..., 2
history = []
for a4 in DENSE:
    record = solve_state(f"N136_lam0_dense_{round(1000 * a4):04d}", 136, 0.0, a4)
    ints = record["emtIntegrals_2Vol7_int_e6Hy"]  # 2 Vol_7 int e^{6Hy} (...) dy
    history.append({"a4": a4, "E": record["E_KS"], "rho": ints["rho"],
                    "p3": ints["p3"], "p_t": ints["p_t"], "p0": ints["p0"],
                    "slope": -3.0 * (ints["p3"] - ints["p_t"])})
```

The free state $N=136$ is solved at the 17 slices $0, 0.125, \ldots, 2$ (the names hold a thousand times the slice with four digits). From each JSON record the cell keeps the energy, the integrals of the

four components that the solver computed on its fine grid, and the slope $-3(\int p_3 - \int p_t)$ that the energy-change law predicts for dE/da_4.

```
adiabatic_rows = read_rows("Revision/kohn_sham/results/adiabatic/adiabaticity.csv")
worst_e, worst_slope = 0.0, 0.0
say("a4,0       E_KS     dE/da4 (EMT)   dE/da4 (record, finite differences)")
for item in history:
    if item["a4"] in (0.0, 0.5, 1.0, 1.5, 2.0):
        key = f"N136_lam0_a{round(10 * item['a4']):02d}"
        recorded_slope = float(adiabatic_rows[key]["dE_da4_finite_difference"])
        worst_e = max(worst_e, rel(item["E"], float(summary_rows[key]["E_KS"])),
                      rel(item["p3"], float(emt_rows[key]["int_p3"])))
        worst_slope = max(worst_slope, rel(item["slope"], recorded_slope))
        say(f"{item['a4']:4.2f}  {item['E']:10.5f}  {item['slope']:12.6f}"
            f"  {recorded_slope:12.6f}")
```

At the five slices of the canonical matrix the cell compares the energy and $\int p_3$ with the record, and the predicted slope with the derivative that the solver obtained from the energies at neighbouring slices (Richardson differences with the step $\delta = 0.002$, column `dE_da4_finite_difference`), and prints a table.

```
report("largest relative difference of E and int p3 to the record", f"{worst_e:.1e}")
report("largest relative difference of the slopes", f"{worst_slope:.1e}")
check(worst_e < 1e-12, "E_KS and the integrals at the five slices equal the record",
      record="Revision/kohn_sham/results/ground/summary.csv and emt-integrals.csv")
check(worst_slope < 1e-8, "dE/da4 = -3 (int p3 - int p_t) at the five slices",
      record="Revision/kohn_sham/results/adiabatic/adiabaticity.csv, column "
             "dE_da4_finite_difference")
```

Out [7]: the energies and integrals equal the record exactly, and the slopes from the pressures agree with the finite differences to 3.7×10^{-12}; the slope is -71.44 at $a_{4,0} = 0$ and -12.19 at $a_{4,0} = 2$.

In [8], the slopes integrated over the history.

```
slopes = np.array([item["slope"] for item in history])
energies = np.array([item["E"] for item in history])
work = simpson(slopes, 0.125)  # integral of dE/da4 over the history
change = energies[-1] - energies[0]
```

Simpson's rule on the 17 slopes (spacing 0.125) integrates dE/da_4 from 0 to 2; the result must equal the change $E(2) - E(0)$ of the energy.

```
fig, ax = plt.subplots()
ax.plot(DENSE, energies, "o", color=PALETTE[0], ms=8, label="$E_{KS}$ (solver)")
for a4, e, s in zip(DENSE, energies, slopes):
    ax.plot([a4 - 0.05, a4 + 0.05], [e - 0.05 * s, e + 0.05 * s], color=PALETTE[1],
            lw=2.5)
ax.plot([], [], color=PALETTE[1], lw=2.0,
        label="slope $-3 \\cdot 2\\mathrm{Vol}_7 \\int e^{6Hy}(p_3 - p_t)$")
```

The energies are drawn as dots; through each dot a short line from $a_{4,0} - 0.05$ to $a_{4,0} + 0.05$ with the predicted slope s (it rises by $0.05\,s$ on each side). An empty plot makes the legend entry.

```
ax.set_xlabel("slice $a_{4,0}$ of the history")
ax.set_ylabel("$E_{KS}$ (units of $m$)")
ax.set_title("$N = 136$, $\\lambda = 0$: the pressures give the slope of the energy")
ax.legend()
save_figure(fig, "energy_slopes",
            "The Kohn-Sham energy $E_{KS}$ of $N = 136$ without interaction "
...)
report("E(2) - E(0) / integral of the slopes", f"{change:.6f} / {work:.6f}")
check(rel(work, change) < 1e-5,
      "the integrated slope equals E(2) - E(0) within 1e-5 (relative)",
      record="Revision/kohn_sham/reports/ks-rust-solver.json, check "
             "emt_energy_change_dE_da4")
```

Figure 15b.4; Out [8]: $E(2) - E(0) = -67.837152$ and the integral of the slopes -67.837207, a relative difference of 8×10^{-7} (the error of Simpson's rule with the coarse spacing 0.125). The energy the gas loses along the history is the work of its pressures.

In [9], the integrated pressure ratios.

```
ratio3 = np.array([item["p3"] / item["rho"] for item in history])
ratio8 = np.array([item["p0"] / item["rho"] for item in history])
fig, ax = plt.subplots()
ax.plot(DENSE, ratio3, color=PALETTE[0], lw=2.0,
        label="$\\int p_3 / \\int \\rho$, $N = 136$")
ax.plot(DENSE, ratio8, color=PALETTE[1], lw=2.0,
        label="$\\int p_0 / \\int \\rho$, $N = 136$")
```

The ratios $\int p_3 / \int \rho$ and $\int p_0 / \int \rho$ at the 17 slices, drawn as lines.

```
worst_ratio = 0.0
for marker, n in (("o", 136), ("s", 688)):
    keys = [f"N{n}_lam0_a{round(10 * a):02d}" for a in (0.0, 0.5, 1.0, 1.5, 2.0)]
    r3 = [float(emt_rows[k]["int_p3"]) / float(emt_rows[k]["int_rho"]) for k in keys]
    r8 = [float(emt_rows[k]["int_p0"]) / float(emt_rows[k]["int_rho"]) for k in keys]
    ax.plot([0, 0.5, 1, 1.5, 2], r3, marker, color=PALETTE[0], ms=8,
            markerfacecolor="white", label=f"record, $N = {n}$")
    ax.plot([0, 0.5, 1, 1.5, 2], r8, marker, color=PALETTE[1], ms=8,
            markerfacecolor="white")
    if n == 136:
        worst_ratio = max(abs(r3[i] - ratio3[4 * i]) for i in range(5))
```

The same ratios from the record's table at the five canonical slices are drawn as open circles ($N = 136$) and squares ($N = 688$). For $N = 136$ they are compared with this notebook's values; `ratio3[4 * i]` is the slice $0.5\,i$, because the dense slices have the spacing 0.125.

```
ax.axhline(1.0 / 3.0, color="0.4", ls=":", lw=1.2, label="$1/3$")
ax.set_xlabel("slice $a_{4,0}$ of the history")
```

```
ax.set_ylabel("ratio of integrals")
ax.set_title("Integrated pressures over integrated energy, $\\lambda = 0$")
ax.legend(fontsize=8)
save_figure(fig, "integrated_ratios",
            "The integrated 3-space pressure (blue) and hidden-direction pressure "
...)
report("int p3 / int rho of N = 136 at a4,0 = 0, 1, 2",
       ", ".join(f"{ratio3[i]:.4f}" for i in (0, 8, 16)))
report("int p0 / int rho of N = 136 at a4,0 = 0, 1, 2",
       ", ".join(f"{ratio8[i]:.4f}" for i in (0, 8, 16)))
check(worst_ratio < 1e-12, "the ratios at the five slices equal the record",
      record=f"{EMT_TABLE}, int_p3 / int_rho")
check(bool(np.all(np.diff(ratio3) > 0.0)) and ratio3[-1] < 1.0 / 3.0,
      "int p3 / int rho rises along the history and stays below 1/3")
```

A dotted line at 1/3, Figure 15b.5, the ratios at $a_{4,0} = 0, 1, 2$ (the dense indices 0, 8, 16) and two checks. Out [9]: $\int p_3 / \int \rho = 0.2966$, 0.3100, 0.3264 and $\int p_0 / \int \rho = 0.4365$, 0.5969, 0.6808; the ratios equal the record, and the 3-space ratio rises at every slice but stays below 1/3 (Section 15.16 explains why).

In [10], where the energy sits.

```
fig, ax = plt.subplots()
means = []
for shade, a4 in zip(SLICE_SHADES, (0.0, 0.5, 1.0, 1.5, 2.0)):
    p = read_profile(repository_file(f"{RECORD_PROFILES}/N136_lam0_a"
                                     f"{round(10 * a4):02d}.csv"))
    density = 2.0 * VOL7 * np.exp(6.0 * H * p["y"]) * p["rho"]
    density = density / simpson(density, step)  # area 1
    means.append(simpson(p["y"] * density, step))
    ax.plot(p["y"], density, color=shade, lw=2.0, label=f"$a_{{4,0}} = {a4}$")
```

For the five committed profiles of $N = 136$ without interaction the energy per unit y, $2\,\mathrm{Vol}_7 e^{6Hy}\rho$, is divided by its integral (so that the area under each curve is 1) and drawn; its mean position $\langle y \rangle = \int y \cdot (\text{density})\, dy$ is computed with Simpson's rule.

```
ax.set_xlabel("hidden coordinate $y$")
ax.set_ylabel("$2\\,\\mathrm{Vol}_7 e^{6Hy}\\rho / E_{KS}$ (units of $m$)")
ax.set_title("The energy spreads toward the tip along the history")
ax.legend()
save_figure(fig, "energy_spreading",
            "The energy per unit $y$ divided by the total energy, "
...)
report("mean position <y> of the energy at the five slices",
       ", ".join(f"{m:.4f}" for m in means))
check(all(means[i + 1] < means[i] for i in range(4)),
      "the mean position of the energy moves toward the tip from slice to slice")
```

Figure 15b.6; Out [10]: $\langle y \rangle = -0.3873$, -0.4263, -0.4556, -0.4746, -0.4849, moving toward the tip from slice to slice, as the redshifted band orbitals spread.

In [11], the interaction terms.

```
sp = read_profile(RUN_FOLDER / "N136_lamp2_a20.csv")
hartree = LAMBDA2_136 * 15.0 / 32.0 * sp["S"] ** 2  # (15/32) lambda S^2
exchange = -LAMBDA2_136 / 32.0 * sp["n"] ** 2  # -(1/32) lambda n^2
fig, ax = plt.subplots()
ax.plot(sp["y"], sp["e_int"], color=PALETTE[0], lw=3.0, label="$e_{int} = p_t$")
ax.plot(sp["y"], hartree, color=PALETTE[1], lw=1.5, ls="--",
        label="$\\frac{15}{32}\\lambda S^2$")
ax.plot(sp["y"], exchange, color=PALETTE[2], lw=1.5, ls="--",
        label="$-\\frac{1}{32}\\lambda n^2$")
ax.set_yscale("symlog", linthresh=1e-2)
```

For the strongly interacting profile the two parts of the interaction energy density are computed from the columns S and n: the positive part $\frac{15}{32}\lambda S^2$ (named `hartree` in the code; it holds the Hartree term and the scalar part of the exchange, Section 15.2) and the negative part $-\frac{1}{32}\lambda n^2$. Both are drawn dashed, with the column e_{int} as a thick line, on a symmetric logarithmic axis.

```
ax.set_xlabel("hidden coordinate $y$")
ax.set_ylabel("proper energy density (units of $m^8$)")
ax.set_title("Interaction energy density, $N = 136$, $+\\lambda_2$, $a_{4,0} = 2$")
ax.legend()
save_figure(fig, "interaction_terms",
            "The interaction energy density $e_{int}$, which is also the extra-time "
...)
sum_error = float(np.max(np.abs(hartree + exchange - sp["e_int"]))) / float(
    np.max(np.abs(sp["e_int"])))
_, _, residual2, integrated2 = conservation(sp)
report("largest |e_int - (15/32 lambda S^2 - 1/32 lambda n^2)| / max|e_int|",
       f"{sum_error:.1e}")
report("conservation law with interaction: pointwise / integrated residual",
       f"{float(np.max(residual2)):.1e} / {integrated2:.1e}")
```

Figure 15b.7; `sum_error` compares the sum of the two parts with the column e_{int}, and the conservation law is evaluated again for this state, in which $p_t \neq 0$.

```
check(sum_error < 1e-12 and bool(np.all(sp["p_t"] == sp["e_int"])),
      "e_int = lambda (15/32 S^2 - 1/32 n^2) and p_t = e_int")
check(float(np.max(residual2)) < 1e-4 and integrated2 < 1e-6,
      "the conservation law holds for the interacting state N136_lamp2_a20",
      record="Revision/kohn_sham/reports/ks-rust-solver.json, checks "
             "emt_y_conservation_pointwise and emt_y_conservation_integrated")
int_pt = [float(row["int_p_t"]) for key, row in emt_rows.items()
          if "_lam0_" not in key]  # the 60 interacting ground states
positive = sum(1 for value in int_pt if value > 0.0)
negative = sum(1 for value in int_pt if value < 0.0)
report("interacting states with integrated p_t > 0 / < 0", f"{positive} / {negative}")
check(len(int_pt) == 60 and positive > 0 and negative > 0,
      "the integrated extra-time pressure takes both signs",
      record=f"{EMT_TABLE}, column int_p_t")
```

Out [11]: the sum matches to 6.8×10^{-16} and $p_t = e_{int}$ exactly; the conservation law holds with residuals 5.0×10^{-6} (pointwise) and 2.3×10^{-8} (integrated). Among the 60 interacting ground states

(every row whose name does not contain `_lam0_`) the integrated extra-time pressure is positive in 29 and negative in 31. In Figure 15b.7 the interaction lives near the tip.

In [12], the three source conditions.

```
import re  # finds the numbers inside the record's text

SOURCE = "Revision/field_equations_a4/reports/ks-source-conditions.json"
source = json.loads(repository_file(SOURCE).read_text(encoding="utf-8"))
details = {item["name"]: item["detail"] for item in source["checks"]}
```

`re` is Python's module for **regular expressions**, patterns that find pieces of text. The source-conditions record is read, and `details` files the detail text of each of its checks under the check name.

```
t_scale = max(float(np.max(np.abs(prof[c]))) for c in ("rho", "p3", "p_t", "p0"))
c1 = (float(np.max(prof["rho"])) - float(np.min(prof["rho"]))) / t_scale  # C1 test
c2 = prof["p3"] + prof["p_t"] - 2.0 * prof["p0"]  # zero everywhere if C2 held
```

For the free profile at $a_{4,0} = 1$: `t_scale` is the largest size of any component, `c1` the variation of ρ along y relative to it (zero if C1 held), and `c2` the array $p_3 + p_t - 2p_0$ (zero everywhere if C2 held).

```
number = r"(-?[0-9.]+(?:e[-+]?[0-9]+)?)"  # a number as the record prints it
examples = re.findall(
    rf"y = {number}: rho = {number}, p3 = {number}, p_t = {number}, "
    rf"p0 = {number}, p3 \+ p_t - 2 p0 = {number}",
    details["ks_profiles_violate_algebraic_condition"])
```

`number` is a pattern for a number as the record prints it: an optional minus sign (`-?`), digits and points (`[0-9.]+`), and an optional exponent such as `e-05`; the parentheses mark the part to be returned. A string with the prefix `rf` is both raw (backslashes are kept) and an f-string, so `{number}` is replaced by the pattern; `\+` stands for a literal plus sign. `re.findall` returns, for every place in the detail text that matches, the six numbers: y, ρ, p_3, p_t, p_0 and $p_3 + p_t - 2p_0$. The record prints three such examples, at $y = -3$, -1.5 and 0.

```
say("    y         rho          p3      p_t          p0  p3 + p_t - 2 p0")
worst_example = 0.0
for example in examples:
    y0, values = float(example[0]), [float(v) for v in example[1:]]
    i = int(np.argmin(np.abs(y - y0)))  # the profile point at this y
    mine = [float(prof["rho"][i]), float(prof["p3"][i]), float(prof["p_t"][i]),
            float(prof["p0"][i]), float(c2[i])]
    say(f"{y[i] + 0.0:5.1f}  {mine[0]:10.6g}  {mine[1]:10.6g}"  # + 0.0 turns -0 into 0
        f"  {mine[2] + 0.0:7.3g}  {mine[3]:10.6g}  {mine[4]:15.6g}")
    for a, b in zip(mine, values):  # 6 significant digits: relative 5e-6
        worst_example = max(worst_example, abs(a - b) / max(abs(b), 1e-300)
                            if b != 0.0 else abs(a))
```

For each example the profile point nearest to its y is found (`np.argmin` gives the position of the smallest distance), this notebook's five values there are printed (the format `g` chooses the shorter of the fixed and the exponent form; adding 0.0 turns a negative zero into 0), and the largest relative difference to the record's six-digit numbers is kept (an absolute difference where the record's value is 0).

```
ratios_c2 = {item["a4"]: (item["p3"] + item["p_t"]) / (2.0 * item["p0"])
             for item in history}
recorded_c2 = {int(key[-2:]) / 10.0: float(value) for key, value in re.findall(
    r"(N136_lam0_a[0-9][0-9]): ([0-9.]+)",
    details["ks_integrals_violate_algebraic_condition"])}
worst_c2 = max(abs(ratios_c2[a4] / value - 1.0) for a4, value in recorded_c2.items())
```

`ratios_c2` holds $(\int p_3 + \int p_t)/(2\int p_0)$ at the 17 slices; C2 integrated would make it 1. The record prints this ratio for `N136_lam0_a00`, `a10` and `a20`; the pattern finds the three names and numbers, the slice is read from the last two digits of the name (`key[-2:]`), and `worst_c2` is the largest relative difference to this notebook's values.

```
report("C1: (max rho - min rho) / max|T| for N136_lam0_a10", f"{c1:.4f}")
report("C2 integrated: (int p3 + int p_t)/(2 int p0) at a4,0 = 0, 1, 2",
       ", ".join(f"{ratios_c2[a]:.6f}" for a in (0.0, 1.0, 2.0)))
report("C3: int rho at a4,0 = 0 and 2; int p3 and int p_t at a4,0 = 1",
       f"{history[0]['rho']:.4f}, {history[-1]['rho']:.4f}; "
       f"{history[8]['p3']:.4f}, {history[8]['p_t']:.1f}")
```

Three RESULT lines: the C1 measure, the C2 ratios at three slices, and the numbers that violate C3 ($\int \rho$ at the first and last slice; $\int p_3$ and $\int p_t$ at $a_{4,0} = 1$).

```
check(c1 > 0.01 and len(examples) == 3 and worst_example < 5e-6
      and float(np.min(np.abs(c2[[0, len(c2) // 2, -1]]))) > 0.0,
      "C1 and C2 fail for N136_lam0_a10; the record's example values reproduced",
      record=f"{SOURCE}, checks ks_profiles_depend_on_x0 and "
             "ks_profiles_violate_algebraic_condition")
check(len(recorded_c2) == 3 and worst_c2 < 5e-6
      and all(abs(r - 1.0) > 0.5 for r in ratios_c2.values()),
      "C2 fails after integration at all 17 slices; the record's ratios reproduced",
      record=f"{SOURCE}, check ks_integrals_violate_algebraic_condition")
check(history[-1]["rho"] < 0.2 * history[0]["rho"]
      and all(item["p3"] > 0.25 * item["rho"] and item["p_t"] == 0.0
              for item in history),
      "C3 fails: rho changes along the history and p3 differs from p_t",
      record=f"{SOURCE}, check ks_history_is_a_prescribed_background")
```

The three checks: C1 and C2 fail for this profile (the variation is more than 1 per cent, and $p_3 + p_t - 2p_0$ is nonzero at the tip, the middle point and the brane; `c2[[0, len(c2) // 2, -1]]` picks these three entries), and the record's three examples are reproduced to six digits; C2 fails after integration at all 17 slices (the ratio differs from 1 by more than 0.5) and the record's three ratios are reproduced; C3 fails ($\int \rho$ falls to less than a fifth, and $\int p_3$ is more than a quarter of $\int \rho$ while $\int p_t = 0$). Out [12] prints the table: at the tip $\rho = 43.07$, $p_3 = 158.3$, $p_0 = -431.7$ and

$p_3 + p_t - 2p_0 = 1021.7$; the C1 measure 0.0998; the C2 ratios 0.339767, 0.259690, 0.239714; and $\int \rho = 80.2822$ and 12.4451.

In [13], the last check.

```
NAMES = ["proper_emt", "coordinate_emt", "y_conservation", "energy_slopes",
         "integrated_ratios", "energy_spreading", "interaction_terms"]
missing = [name for number, name in enumerate(NAMES, start=1)
           if not output_file(f"{FIGURE_FOLDER}/15b_{number}_{name}.png").is_file()]
check(missing == [], "every figure file of this notebook exists")
all_checks_passed()
```

As in Notebook 15e (Section 15.9, In [15]), with the seven figure names of this notebook in order and the file names `15b_<number>_<name>.png`: the names whose file does not exist are collected, the check requires that list to be empty, and `all_checks_passed()` prints the last line, ALL 18 CHECKS PASSED (notebook 15b).

15.21 Adiabaticity: does the gas follow the moving background?

The question. Every state computed so far is an **instantaneous** state: at the slice $a_{4,0}$ the solver finds the ground state of the Hamiltonian $h(a_{4,0})$ of that instant, as if the background stood still. But it does not stand still: along the history $a_4 = AHx_4$ grows with the time x_4, 3-space inflates and the extra times deflate. A system whose Hamiltonian changes slowly enough stays in the eigenstate that continues its initial one (the **adiabatic theorem** of quantum mechanics; Chapter 14 introduced this adiabatic picture); a system whose Hamiltonian changes too fast is kicked into higher levels. Which case applies here must be measured.

The exact evolution keeps the sector. In the mean field the orbitals obey exactly (ks-theory.json, adiabaticity.exactEvolution; check ansatz_removes_spin_connection, which holds for a time-dependent a_4)

$$i\,\frac{\partial \chi}{\partial x_4} = h(a_4(x_4))\,\chi, \qquad h_j = j\Big[-i\sigma_1\frac{d}{dy} + M\sigma_2 + \kappa k\sigma_3\Big] + v, \qquad \kappa = e^{-Hy-a_4(x_4)}.$$

At every instant h acts within one block, at one 3-momentum, and keeps the brane condition; so the evolution never moves a particle to another momentum, block type or parity. **Transitions are possible only inside a sector**, between the levels of one (n_2, j, parity). Notebook 15a showed that each of the lowest particle-hole excitations of the gas (up to 24 per state, 1610 in all) changes the sector (Section 15.15); the in-sector jumps are much more expensive: the one with the largest Q costs between $1.488\,m$ and $2.253\,m$ in the 50 states that have one (all but the 25 states with $N = 8$).

Where the measure Q comes from, line by line. Expand the evolving orbital in the instantaneous orbitals ϕ_m, with $h\,\phi_m = \varepsilon_m\phi_m$ at every instant, as $\chi = \sum_m c_m(x_4)\,e^{-i\theta_m}\phi_m$ with the phases $\theta_m = \int^{x_4} \varepsilon_m\,dx_4$; a dot means d/dx_4.

$$i\dot\chi = \sum_m \left(i\dot c_m + \varepsilon_m c_m\right)e^{-i\theta_m}\phi_m + i\sum_m c_m e^{-i\theta_m}\dot\phi_m.$$

Rule: the product rule for the three factors; $\dot\theta_m = \varepsilon_m$.

$$h\chi = \sum_m \varepsilon_m c_m e^{-i\theta_m}\phi_m.$$

Rule: $h\phi_m = \varepsilon_m\phi_m$.

$$\dot c_m = -\sum_n c_n\, e^{i(\theta_m-\theta_n)}\,\langle m|\dot\phi_n\rangle.$$

Rule: set the two lines equal (the evolution equation), the terms $\varepsilon_m c_m$ cancel, take the inner product with ϕ_m (the orbitals are orthonormal, so $\langle m|\phi_n\rangle$ is 1 for $n=m$ and 0 otherwise; $\langle m|X\rangle$ means $\int \phi_m^\dagger X\,dy$), multiply by $-i\,e^{i\theta_m}$, and use $-i\cdot i = 1$.

$$\langle m|\dot\phi_n\rangle = \frac{\langle m|\dot h|n\rangle}{\varepsilon_n-\varepsilon_m} = \dot a_4\,\frac{\langle m|\partial_a h|n\rangle}{\varepsilon_n-\varepsilon_m} \qquad (m\neq n).$$

Rule: differentiate $h\phi_n = \varepsilon_n\phi_n$: $\dot h\phi_n + h\dot\phi_n = \dot\varepsilon_n\phi_n + \varepsilon_n\dot\phi_n$; take the inner product with ϕ_m, where $\langle m|h\dot\phi_n\rangle = \varepsilon_m\langle m|\dot\phi_n\rangle$ (h is self-adjoint, Section 15.2) and $\langle m|\phi_n\rangle = 0$; solve for $\langle m|\dot\phi_n\rangle$; finally $\dot h = \dot a_4\,\partial h/\partial a_4$ (chain rule), written $\partial_a h$ (check adiabatic_offdiagonal_identity).

$$|c_m| \approx \Big|\int \dot a_4\,\frac{\langle m|\partial_a h|n\rangle}{\varepsilon_n-\varepsilon_m}\,e^{i(\varepsilon_m-\varepsilon_n)x_4}\,dx_4\Big| \approx \dot a_4\,\frac{|\langle m|\partial_a h|n\rangle|}{(\varepsilon_n-\varepsilon_m)^2}.$$

Rule: start with $c_n = 1$ and all other c zero, and keep on the right of the third line only the term of the occupied orbital n (first order); over a short stretch of time the factor in front of the exponential hardly changes, and $\int e^{i\omega x_4}dx_4 = e^{i\omega x_4}/(i\omega)$, whose size is $1/|\omega|$ with $\omega = \varepsilon_m-\varepsilon_n$.

With $\dot a_4 = AH$ this is the **adiabaticity measure** of the record (ks-theory.json, adiabaticity.measure):

$$Q_{nm} = AH\,\frac{|\langle n|\partial_a h|m\rangle|}{(\varepsilon_n-\varepsilon_m)^2}, \qquad \text{transition probability} \approx Q_{nm}^2,$$

for n occupied and m empty in the same sector. The evolution is adiabatic when every $Q_{nm} \ll 1$. This is an estimate of first order, not a solution of the time-dependent problem, which stays OPEN.

The derivative of the Hamiltonian. Without interaction only κ depends on a_4, and $\partial\kappa/\partial a_4 = -\kappa$ (the derivative of e^{-Hy-a_4}). So

$$\partial_a h_j = -j\,\kappa k\,\sigma_3, \qquad \langle n|\partial_a h|m\rangle = -j\,k\,e^{-a_{4,0}}\int_{-L}^{0} e^{-Hy}\,(a_n a_m - b_n b_m)\,dy,$$

because for $\chi = (a, ib)$ the product $\chi_n^\dagger\sigma_3\chi_m$ is $a_n a_m + (-ib_n)(-ib_m) = a_n a_m - b_n b_m$. With interaction the self-consistent potentials change with a_4 too, and $\partial_a h$ gains $j(\partial_a M)\sigma_2 + \partial_a v$, which the solver obtains from the states at $a_{4,0}\pm\delta$ and $\pm 2\delta$ (ks-theory.json, adiabaticity.derivative). At $k=0$, $\partial_a h = 0$: the zero modes do not feel the history at all, and for $N=8$ every Q is exactly zero.

Hellmann-Feynman. For $m=n$ the same differentiation gives the **Hellmann-Feynman theorem** of Chapter 13, $d\varepsilon_n/da_4 = \langle n|\partial_a h|n\rangle$ (take the inner product of the differentiated eigenequation with ϕ_n itself; the terms with $\dot\phi_n$ cancel because h is self-adjoint and $\langle n|n\rangle = 1$). Summed

over the occupied levels it gives $dE/da_4 = \sum g f \langle n|\partial_a h|n\rangle$ for the free gas, the same as the energy-change law of Section 15.16 (check adiabatic_hellmann_feynman of `Revision/kohn_sham/reports/ks-theory-python.json`; the solver checks it for all 75 states, worst deviation $2.6 \times 10^{-9}\,m$, check adiabatic_hellmann_feynman of `Revision/kohn_sham/reports/ks-rust-solver.json`).

What the record finds (COMPUTED; `Revision/kohn_sham/results/adiabatic/adiabaticity.csv`, reproduced by Notebook 15c). Over the whole canonical matrix $Q_{max} \leq 0.0935$, so every transition probability is below 0.009; the largest Q belongs to the jump from the brane-band level of the highest occupied shell to the first bulk level of the same sector, at the start of the history ($N = 688$, $a_{4,0} = 0$), and Q_{max} falls along the history because the matrix element carries the factor $k\,e^{-a_{4,0}}$. Within the sectors, the instantaneous states are followed adiabatically to a good approximation.

Fermi-level crossings. Adiabatic evolution keeps the occupation of every level. If along the history an empty level of one sector comes down below an occupied level of another sector, the instantaneous ground state (aufbau) would move particles from one to the other, but the evolution cannot: the two levels lie in different sectors. Such a **Fermi-level crossing** makes the instantaneous ground state the wrong state. The canonical matrix has none (the record file `adiabatic/fermi-level-crossings.csv`: no change of the occupied set in any of its 60 rows). The record demonstrates the effect with $N = 696 = 688 + 8$ (check adiabatic_crossing_flag_demonstration): at $a_{4,0} = 0$ the eight extra particles sit in the odd bulk level at $k = 0$ ($\varepsilon = 1.2923$, which does not move), while the band level of the shell $n_2 = 12$ lies just above it and comes down; after the crossing the adiabatically continued state lies above the instantaneous aufbau state by $3.66\,m$ at $a_{4,0} = 0.5$, growing to $8.62\,m$ at $a_{4,0} = 2$ (`adiabatic/crossing-demo.csv`). There the instantaneous picture fails.

15.22 Example: the adiabaticity measure (Notebook 15c)

Notebook 15c needs no Rust. It defines the solver's shooting method for the free problem in Python, solves again all 270 levels of the occupied sectors of the free states $N = 136$ and $N = 688$ at the five slices, and computes Q_{nm} for every allowed pair. It draws the two orbitals of the pair with the largest Q and the integrand of their matrix element (Figure 15c.1), every Q against the shell (Figure 15c.2), Q_{max} of the whole matrix along the history (Figure 15c.3), the Hellmann-Feynman theorem (Figure 15c.4), the Fermi-level crossing of $N = 696$ (Figure 15c.5) and a heat map of Q_{max} (Figure 15c.6). It takes about 15 seconds and ends with ALL 12 CHECKS PASSED (notebook 15c).

What to look for: in Figure 15c.1 that the band orbital sits at the brane while the bulk orbital fills the interval, so that their overlap is small; in Figure 15c.2 that all points lie below 0.1; in Figure 15c.5 how quickly the band level crosses the fixed bulk level.

15.23 How to run Notebook 15c

Step 1. What this notebook does and what it needs.

Notebook 15c (Adiabaticity along the deflating history) is the file `Revision/textbook/notebooks/15c_adiabaticity.ipynb` of the repository Dirac_claude. It explains when the instantaneous Kohn-Sham states of dirac16complex can be followed along the deflating history (the adiabatic approximation), recomputes in plain Python the adiabaticity measure Q of every allowed transition of the free states N = 136 and N = 688 at the five slices, reproduces the largest Q, its pair of

levels, its energy difference and its matrix element from the committed Revision record, checks the Hellmann-Feynman theorem and the energy derivative along the history, and reproduces the Fermi-level crossing of the demonstration state N = 696. It needs a computer with Windows 11, macOS or Linux, an internet connection for the installation, the program Git, and Python 3.12 or newer (the notebooks were built with Python 3.14.5) with these packages at exactly these versions: numpy 2.4.6, sympy 1.14.0, mpmath 1.3.0, matplotlib 3.11.0, jupyterlab 4.4.10, nbformat 5.10.4, nbclient 0.10.2, ipykernel 7.1.0 and nbconvert 7.16.6. The notebook itself imports numpy and matplotlib; the other packages run Jupyter, the program that shows and runs notebooks. It does not need Rust.

Step 2. Install Git and Python (once per computer).

A terminal is the window in which you type commands: on Windows the app Windows PowerShell (or Terminal), on macOS the app Terminal (it runs the shell zsh), on Linux any terminal (it runs the shell bash). Type every command of this section into a terminal exactly as printed, one line at a time, and press Enter after each line.

Windows: download Git from https://git-scm.com/download/win and install it with the default choices. Download Python from https://www.python.org/downloads/ and run the installer; in its first window tick the box "Add python.exe to PATH" before you click "Install Now".

macOS: download Python from https://www.python.org/downloads/ and run the installer. Then open the app Terminal and run this command, which installs Git and the compiler tools:

macOS (zsh):

```
xcode-select --install
```

Linux (Debian or Ubuntu; other distributions have packages of the same names): run these two commands:

Linux (bash):

```
sudo apt update
sudo apt install git python3 python3-venv
```

Then close the terminal and open a NEW one (a terminal opened before the installation does not know the new programs), and check the version of Python; it must print 3.12 or a higher number:

Windows (PowerShell):

```
py -3 --version
```

macOS (zsh) and Linux (bash):

```
python3 --version
```

If an older Linux prints a lower number (Ubuntu 22.04 has Python 3.10), install Python 3.12 with the following three commands, and in Step 3 type `python3.12` instead of `python3` in the command that creates the environment:

Linux (bash), only when the version is too low:

```
sudo add-apt-repository ppa:deadsnakes/ppa
sudo apt update
sudo apt install python3.12 python3.12-venv
```

Step 3. Get the repository and install the packages (once per computer).

The commands below download the repository (a few hundred megabytes; the folder then needs up to about 1 GB of disk space) into the folder Dirac_claude inside your home folder, create a private Python environment in the folder dirac-book-env inside your home folder (a private environment is a folder with its own copy of Python and of the packages, so that nothing else on your computer is changed), activate it (from then on the commands `python` and `jupyter` typed in this terminal are those of the environment, and the prompt starts with (dirac-book-env)), and install the packages at the pinned versions (this downloads about 90 MB and takes a few minutes; the environment takes about 400 MB of disk space). If you have done this step before, for this or for another notebook, skip it and go to Step 4; to get the newest version of the repository, run `git pull` in the repository folder after Step 4.

Windows (PowerShell):

```
cd $HOME
git clone https://github.com/once-ere/Dirac_claude.git
py -3 -m venv "$HOME\dirac-book-env"
Set-ExecutionPolicy -ExecutionPolicy RemoteSigned -Scope Process -Force
& "$HOME\dirac-book-env\Scripts\Activate.ps1"
python -m pip install --upgrade pip
python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
```

The line with `Set-ExecutionPolicy` allows PowerShell to run the activation script in this one window only; it changes nothing permanently.

macOS (zsh):

```
cd ~
git clone https://github.com/once-ere/Dirac_claude.git
python3 -m venv ~/dirac-book-env
source ~/dirac-book-env/bin/activate
python -m pip install --upgrade pip
python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
```

Linux (bash):

```
cd ~
git clone https://github.com/once-ere/Dirac_claude.git
python3 -m venv ~/dirac-book-env
source ~/dirac-book-env/bin/activate
python -m pip install --upgrade pip
```

```
python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
```

Step 4. In every new terminal: activate the environment and go into the repository folder.

Every later step starts in the repository folder with the environment active. Run these lines whenever you open a new terminal (they do no harm if the environment is already active):

Windows (PowerShell):

```
Set-ExecutionPolicy -ExecutionPolicy RemoteSigned -Scope Process -Force
& "$HOME\dirac-book-env\Scripts\Activate.ps1"
cd "$HOME\Dirac_claude"
```

macOS (zsh) and Linux (bash):

```
source ~/dirac-book-env/bin/activate
cd ~/Dirac_claude
```

Step 5. Run the notebook in JupyterLab.

In the repository folder, with the environment active, run these two lines (the first one goes into the folder of the notebooks):

Windows, macOS and Linux:

```
cd Revision/textbook/notebooks
jupyter lab 15c_adiabaticity.ipynb
```

JupyterLab opens in your web browser and shows the notebook (if no browser window opens, copy the address that starts with `http://localhost:8888/lab` from the terminal into the address bar of your browser). The name at the top right of the notebook must read Python 3 (ipykernel). Choose the menu Run > Run All Cells. While a cell runs, the label to its left shows `[*]`; when it has finished, the label shows a number. The notebook has finished when the last code cell shows a number; this takes about 15 seconds on a typical laptop. Scroll to the end and compare the last printed lines with the lines in the step "What the notebook writes and what you must see" below. To keep the results, save the notebook (menu File > Save Notebook). To stop JupyterLab, choose the menu File > Shut Down, or press Ctrl+C twice in the terminal.

Step 6. Or run the notebook without a browser (headless).

In the repository folder, with the environment active, run:

Windows, macOS and Linux:

```
cd Revision/textbook/notebooks
jupyter nbconvert --to notebook --execute --inplace 15c_adiabaticity.ipynb
```

This runs every cell from the top to the bottom and saves the results into the notebook file. A failed check stops it with an error message that contains AssertionError and the name of the check. If the command ends with a line that starts with `[NbConvertApp] Writing` and shows no error, every check passed; open the notebook with `jupyter lab 15c_adiabaticity.ipynb` (in the same folder, without running the cells again) to read the printed lines and see the figures.

Step 7. What the notebook writes and what you must see.

The notebook writes (or overwrites) these files:

- `Revision/textbook/figures/15c.captions.json`
- `Revision/textbook/figures/15c_1_transition_orbitals.png`
- `Revision/textbook/figures/15c_2_q_by_pair.png`
- `Revision/textbook/figures/15c_3_q_history.png`
- `Revision/textbook/figures/15c_4_hellmann_feynman.png`
- `Revision/textbook/figures/15c_5_fermi_crossing.png`
- `Revision/textbook/figures/15c_6_q_map.png`

It changes no other file of the repository; running it headless or saving it in JupyterLab also rewrites the notebook file itself. It does not use the internet while it runs. The files it writes are the same files that are stored in the repository (on another computer a figure may differ in a few bytes, which is harmless). To get the stored versions back, run this command in the repository folder (it also undoes every change you made yourself in the folder Revision/textbook):

Windows, macOS and Linux:

```
git checkout -- Revision/textbook
```

Every check of the notebook prints a line that starts with PASS. At the end of the notebook (the output of its last code cell) you must see exactly these lines:

```
PASS every figure file of this notebook exists
ALL 12 CHECKS PASSED (notebook 15c)
```

and the notebook must show 6 figures below the cells that draw them.

Step 8. If something goes wrong.

- "ModuleNotFoundError: No module named ..." in the notebook: JupyterLab was started without the environment. Stop it (menu File > Shut Down), do Step 4, and start it again. If the error remains, another Python installation has registered its own kernel called python3; with the environment active, run the following command and start JupyterLab again:

```
python -m ipykernel install --user --name python3
```

- "FileNotFoundError: The repository folder was not found": the notebook was opened from a copy outside the repository. Open the file `Revision/textbook/notebooks/15c_adiabaticity.ipynb` inside the folder Dirac_claude.
- "fatal: destination path 'Dirac_claude' already exists" in Step 3: the repository was downloaded before; skip the line with `git clone`.
- Windows: "running scripts is disabled on this system": run the line with `Set-ExecutionPolicy` and then the activation line again. "py is not recognized": use `python` instead of `py -3`; "python is not recognized": install Python again and tick "Add python.exe to PATH".
- Linux: "ensurepip is not available" when the environment is created: run `sudo apt install python3-venv` and repeat Step 3.
- "jupyter is not recognized" or "command not found: jupyter": the environment is not active; do Step 4. If the environment is active and the message stays, the programs jupyter-lab and jupyter-nbconvert are not in the folders where the terminal looks for programs (`python -m jupyter` does not help then: it has to find the same programs). Start them through Python itself, in the folder of the notebook: the first command below does what `jupyter lab` does, the second what the headless command does:

```
python -m jupyterlab 15c_adiabaticity.ipynb
python -m nbconvert --execute --inplace 15c_adiabaticity.ipynb
```

- Windows: the headless run prints a RuntimeWarning that mentions the "Proactor event loop" and zmq: this is a message of the package pyzmq, not an error; the run continues normally.
- A red box with "Matplotlib is building the font cache; this may take a moment." in the first run after the installation: this is a message, not an error; the run continues and the message does not come again.
- An AssertionError names a check that failed: choose the menu Kernel > Restart Kernel and Run All Cells; if it fails again, install the packages again with the pip commands of Step 3, because a different package version can change the last digits of a result.

15.24 Notebook 15c: complete text

This section prints the complete text of the notebook file `Revision/textbook/notebooks/15c_adiabaticity.ipynb`: every cell in order, with the output that the stored, executed notebook holds. A text cell (Jupyter calls it a markdown cell) is printed in a frame after the label Text cell. A code cell is printed after the label In [k], where k is the number that Jupyter gives the cell when it runs it; the text that the cell prints follows after the label Out [k], and every figure that the cell draws follows as a figure with its caption.

Text cell:

```
## 1. What this notebook computes

The Kohn-Sham states of the Revision record are **instantaneous** states: at each
```

```
slice $a_{4,0}$ of the history the solver finds the ground state of the Hamiltonian
of that instant. But the history moves on: $a_4 = A H x_4$ grows with the time
$x_4$. Does the gas follow the instantaneous ground state, or does the motion of
the background kick particles into higher levels? This is the question of
**adiabaticity**. This notebook

- explains the measure $Q_{nm}$ of the Revision record and where it comes from;
- recomputes in plain Python, with the solver's own shooting method, every
  allowed transition of the free states $N = 136$ and $N = 688$ at the five slices,
  and reproduces the largest value $Q_{max}$, the pair of levels, their energy
  difference and the matrix element recorded by the Rust solver;
- checks the Hellmann-Feynman theorem $d\varepsilon_n/da_4 = \langle n|\partial_a
  h|n\rangle$ and the energy derivative $dE/da_4$;
- reproduces the **Fermi-level crossing** of the demonstration state $N = 696$, where
  the instantaneous ground state and the adiabatically followed state differ.

It draws six figures and needs no Rust.
```

Text cell:

```
## 2. How to run this notebook

**Step 1. What this notebook does and what it needs.**

Notebook 15c (Adiabaticity along the deflating history) is the file
‘Revision/textbook/notebooks/15c_adiabaticity.ipynb‘ of the repository Dirac_claude. It
explains when the instantaneous Kohn-Sham states of dirac16complex can be followed along
the deflating history (the adiabatic approximation), recomputes in plain Python the
adiabaticity measure Q of every allowed transition of the free states N = 136 and N = 688
at the five slices, reproduces the largest Q, its pair of levels, its energy difference
and its matrix element from the committed Revision record, checks the Hellmann-Feynman
theorem and the energy derivative along the history, and reproduces the Fermi-level
crossing of the demonstration state N = 696. It needs a computer with Windows 11, macOS
or Linux, an internet connection for the installation, the program Git, and Python 3.12
or newer (the notebooks were built with Python 3.14.5) with these packages at exactly
these versions: numpy 2.4.6, sympy 1.14.0, mpmath 1.3.0, matplotlib 3.11.0, jupyterlab
4.4.10, nbformat 5.10.4, nbclient 0.10.2, ipykernel 7.1.0 and nbconvert 7.16.6. The
notebook itself imports numpy and matplotlib; the other packages run Jupyter, the program
that shows and runs notebooks. It does not need Rust.

**Step 2. Install Git and Python (once per computer).**

A terminal is the window in which you type commands: on Windows the app Windows
PowerShell (or Terminal), on macOS the app Terminal (it runs the shell zsh), on Linux any
terminal (it runs the shell bash). Type every command of this section into a terminal
exactly as printed, one line at a time, and press Enter after each line.

Windows: download Git from https://git-scm.com/download/win and install it with the
default choices. Download Python from https://www.python.org/downloads/ and run the
installer; in its first window tick the box "Add python.exe to PATH" before you click
"Install Now".

macOS: download Python from https://www.python.org/downloads/ and run the installer. Then
```

open the app Terminal and run this command, which installs Git and the compiler tools:

macOS (zsh):

```
    xcode-select --install
```

Linux (Debian or Ubuntu; other distributions have packages of the same names): run these two commands:

Linux (bash):

```
    sudo apt update
    sudo apt install git python3 python3-venv
```

Then close the terminal and open a NEW one (a terminal opened before the installation does not know the new programs), and check the version of Python; it must print 3.12 or a higher number:

Windows (PowerShell):

```
    py -3 --version
```

macOS (zsh) and Linux (bash):

```
    python3 --version
```

If an older Linux prints a lower number (Ubuntu 22.04 has Python 3.10), install Python 3.12 with the following three commands, and in Step 3 type ‘python3.12‘ instead of ‘python3‘ in the command that creates the environment:

Linux (bash), only when the version is too low:

```
    sudo add-apt-repository ppa:deadsnakes/ppa
    sudo apt update
    sudo apt install python3.12 python3.12-venv
```

Step 3. Get the repository and install the packages (once per computer).

The commands below download the repository (a few hundred megabytes; the folder then needs up to about 1 GB of disk space) into the folder Dirac_claude inside your home folder, create a private Python environment in the folder dirac-book-env inside your home folder (a private environment is a folder with its own copy of Python and of the packages, so that nothing else on your computer is changed), activate it (from then on the commands ‘python‘ and ‘jupyter‘ typed in this terminal are those of the environment, and the prompt starts with (dirac-book-env)), and install the packages at the pinned versions (this downloads about 90 MB and takes a few minutes; the environment takes about 400 MB of disk space). If you have done this step before, for this or for another notebook, skip it and go to Step 4; to get the newest version of the repository, run ‘git pull‘ in the repository folder after Step 4.

Windows (PowerShell):

```
    cd $HOME
    git clone https://github.com/once-ere/Dirac_claude.git
```

```
    py -3 -m venv "$HOME\dirac-book-env"
    Set-ExecutionPolicy -ExecutionPolicy RemoteSigned -Scope Process -Force
    & "$HOME\dirac-book-env\Scripts\Activate.ps1"
    python -m pip install --upgrade pip
    python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
    python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
    python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
```

The line with ‘Set-ExecutionPolicy‘ allows PowerShell to run the activation script in this one window only; it changes nothing permanently.

macOS (zsh):

```
    cd ~
    git clone https://github.com/once-ere/Dirac_claude.git
    python3 -m venv ~/dirac-book-env
    source ~/dirac-book-env/bin/activate
    python -m pip install --upgrade pip
    python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
    python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
    python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
```

Linux (bash):

```
    cd ~
    git clone https://github.com/once-ere/Dirac_claude.git
    python3 -m venv ~/dirac-book-env
    source ~/dirac-book-env/bin/activate
    python -m pip install --upgrade pip
    python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
    python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
    python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
```

Step 4. In every new terminal: activate the environment and go into the repository folder.

Every later step starts in the repository folder with the environment active. Run these lines whenever you open a new terminal (they do no harm if the environment is already active):

Windows (PowerShell):

```
    Set-ExecutionPolicy -ExecutionPolicy RemoteSigned -Scope Process -Force
    & "$HOME\dirac-book-env\Scripts\Activate.ps1"
    cd "$HOME\Dirac_claude"
```

macOS (zsh) and Linux (bash):

```
    source ~/dirac-book-env/bin/activate
    cd ~/Dirac_claude
```

Step 5. Run the notebook in JupyterLab.

In the repository folder, with the environment active, run these two lines (the first one

goes into the folder of the notebooks):

Windows, macOS and Linux:

```
cd Revision/textbook/notebooks
jupyter lab 15c_adiabaticity.ipynb
```

JupyterLab opens in your web browser and shows the notebook (if no browser window opens, copy the address that starts with ‘http://localhost:8888/lab‘ from the terminal into the address bar of your browser). The name at the top right of the notebook must read Python 3 (ipykernel). Choose the menu Run > Run All Cells. While a cell runs, the label to its left shows ‘[*]‘; when it has finished, the label shows a number. The notebook has finished when the last code cell shows a number; this takes about 15 seconds on a typical laptop. Scroll to the end and compare the last printed lines with the lines in the step "What the notebook writes and what you must see" below. To keep the results, save the notebook (menu File > Save Notebook). To stop JupyterLab, choose the menu File > Shut Down, or press Ctrl+C twice in the terminal.

Step 6. Or run the notebook without a browser (headless).

In the repository folder, with the environment active, run:

Windows, macOS and Linux:

```
cd Revision/textbook/notebooks
jupyter nbconvert --to notebook --execute --inplace 15c_adiabaticity.ipynb
```

This runs every cell from the top to the bottom and saves the results into the notebook file. A failed check stops it with an error message that contains AssertionError and the name of the check. If the command ends with a line that starts with ‘[NbConvertApp] Writing‘ and shows no error, every check passed; open the notebook with ‘jupyter lab 15c_adiabaticity.ipynb‘ (in the same folder, without running the cells again) to read the printed lines and see the figures.

Step 7. What the notebook writes and what you must see.

The notebook writes (or overwrites) these files:

- ‘Revision/textbook/figures/15c.captions.json‘
- ‘Revision/textbook/figures/15c_1_transition_orbitals.png‘
- ‘Revision/textbook/figures/15c_2_q_by_pair.png‘
- ‘Revision/textbook/figures/15c_3_q_history.png‘
- ‘Revision/textbook/figures/15c_4_hellmann_feynman.png‘
- ‘Revision/textbook/figures/15c_5_fermi_crossing.png‘
- ‘Revision/textbook/figures/15c_6_q_map.png‘

It changes no other file of the repository; running it headless or saving it in JupyterLab also rewrites the notebook file itself. It does not use the internet while it runs. The files it writes are the same files that are stored in the repository (on another computer a figure may differ in a few bytes, which is harmless). To get the stored versions back, run this command in the repository folder (it also undoes every change you made yourself in the folder Revision/textbook):

Windows, macOS and Linux:

```
    git checkout -- Revision/textbook
```

Every check of the notebook prints a line that starts with PASS. At the end of the notebook (the output of its last code cell) you must see exactly these lines:

```
    PASS every figure file of this notebook exists
    ALL 12 CHECKS PASSED (notebook 15c)
```

and the notebook must show 6 figures below the cells that draw them.

Step 8. If something goes wrong.

- "ModuleNotFoundError: No module named ..." in the notebook: JupyterLab was started without the environment. Stop it (menu File > Shut Down), do Step 4, and start it again. If the error remains, another Python installation has registered its own kernel called python3; with the environment active, run the following command and start JupyterLab again:

  ```
      python -m ipykernel install --user --name python3
  ```

- "FileNotFoundError: The repository folder was not found": the notebook was opened from a copy outside the repository. Open the file ‘Revision/textbook/notebooks/15c_adiabaticity.ipynb‘ inside the folder Dirac_claude.
- "fatal: destination path ’Dirac_claude’ already exists" in Step 3: the repository was downloaded before; skip the line with ‘git clone‘.
- Windows: "running scripts is disabled on this system": run the line with ‘Set-ExecutionPolicy‘ and then the activation line again. "py is not recognized": use ‘python‘ instead of ‘py -3‘; "python is not recognized": install Python again and tick "Add python.exe to PATH".
- Linux: "ensurepip is not available" when the environment is created: run ‘sudo apt install python3-venv‘ and repeat Step 3.
- "jupyter is not recognized" or "command not found: jupyter": the environment is not active; do Step 4. If the environment is active and the message stays, the programs jupyter-lab and jupyter-nbconvert are not in the folders where the terminal looks for programs (‘python -m jupyter‘ does not help then: it has to find the same programs). Start them through Python itself, in the folder of the notebook: the first command below does what ‘jupyter lab‘ does, the second what the headless command does:

  ```
      python -m jupyterlab 15c_adiabaticity.ipynb
      python -m nbconvert --execute --inplace 15c_adiabaticity.ipynb
  ```

- Windows: the headless run prints a RuntimeWarning that mentions the "Proactor event loop" and zmq: this is a message of the package pyzmq, not an error; the run continues normally.
- A red box with "Matplotlib is building the font cache; this may take a moment." in the first run after the installation: this is a message, not an error; the run continues and the message does not come again.
- An AssertionError names a check that failed: choose the menu Kernel > Restart Kernel and Run All Cells; if it fails again, install the packages again with the pip commands of Step 3, because a different package version can change the last digits of a result.

The first code cell below (the set-up cell) repeats these instructions as comments; then it imports the packages, finds the repository folder and defines the helpers

‘save_figure‘ (saves a figure and shows it), ‘check‘ (stops with an AssertionError when a check fails, prints a PASS line when it passes), ‘report‘ (prints a key number as a RESULT line) and ‘all_checks_passed‘ (prints the last line).

In [1]:

```
# HOW TO RUN NOTEBOOK 15c (the complete instructions)
#
# STEP 1. WHAT THIS NOTEBOOK DOES AND WHAT IT NEEDS.
#
# Notebook 15c (Adiabaticity along the deflating history) is the file
# Revision/textbook/notebooks/15c_adiabaticity.ipynb of the repository Dirac_claude. It
# explains when the instantaneous Kohn-Sham states of dirac16complex can be followed
# along the deflating history (the adiabatic approximation), recomputes in plain Python
# the adiabaticity measure Q of every allowed transition of the free states N = 136 and N
# = 688 at the five slices, reproduces the largest Q, its pair of levels, its energy
# difference and its matrix element from the committed Revision record, checks the
# Hellmann-Feynman theorem and the energy derivative along the history, and reproduces
# the Fermi-level crossing of the demonstration state N = 696. It needs a computer with
# Windows 11, macOS or Linux, an internet connection for the installation, the program
# Git, and Python 3.12 or newer (the notebooks were built with Python 3.14.5) with these
# packages at exactly these versions: numpy 2.4.6, sympy 1.14.0, mpmath 1.3.0, matplotlib
# 3.11.0, jupyterlab 4.4.10, nbformat 5.10.4, nbclient 0.10.2, ipykernel 7.1.0 and
# nbconvert 7.16.6. The notebook itself imports numpy and matplotlib; the other packages
# run Jupyter, the program that shows and runs notebooks. It does not need Rust.
#
# STEP 2. INSTALL GIT AND PYTHON (ONCE PER COMPUTER).
#
# A terminal is the window in which you type commands: on Windows the app Windows
# PowerShell (or Terminal), on macOS the app Terminal (it runs the shell zsh), on Linux
# any terminal (it runs the shell bash). Type every command of this section into a
# terminal exactly as printed, one line at a time, and press Enter after each line.
#
# Windows: download Git from https://git-scm.com/download/win and install it with the
# default choices. Download Python from https://www.python.org/downloads/ and run the
# installer; in its first window tick the box "Add python.exe to PATH" before you click
# "Install Now".
#
# macOS: download Python from https://www.python.org/downloads/ and run the installer.
# Then open the app Terminal and run this command, which installs Git and the compiler
# tools:
#
# macOS (zsh):
#     xcode-select --install
#
# Linux (Debian or Ubuntu; other distributions have packages of the same names): run
# these two commands:
#
# Linux (bash):
#     sudo apt update
#     sudo apt install git python3 python3-venv
#
# Then close the terminal and open a NEW one (a terminal opened before the installation
```

```
# does not know the new programs), and check the version of Python; it must print 3.12 or
# a higher number:
#
# Windows (PowerShell):
#     py -3 --version
#
# macOS (zsh) and Linux (bash):
#     python3 --version
#
# If an older Linux prints a lower number (Ubuntu 22.04 has Python 3.10), install Python
# 3.12 with the following three commands, and in Step 3 type python3.12 instead of
# python3 in the command that creates the environment:
#
# Linux (bash), only when the version is too low:
#     sudo add-apt-repository ppa:deadsnakes/ppa
#     sudo apt update
#     sudo apt install python3.12 python3.12-venv
#
# STEP 3. GET THE REPOSITORY AND INSTALL THE PACKAGES (ONCE PER COMPUTER).
#
# The commands below download the repository (a few hundred megabytes; the folder then
# needs up to about 1 GB of disk space) into the folder Dirac_claude inside your home
# folder, create a private Python environment in the folder dirac-book-env inside your
# home folder (a private environment is a folder with its own copy of Python and of the
# packages, so that nothing else on your computer is changed), activate it (from then on
# the commands python and jupyter typed in this terminal are those of the environment,
# and the prompt starts with (dirac-book-env)), and install the packages at the pinned
# versions (this downloads about 90 MB and takes a few minutes; the environment takes
# about 400 MB of disk space). If you have done this step before, for this or for another
# notebook, skip it and go to Step 4; to get the newest version of the repository, run
# git pull in the repository folder after Step 4.
#
# Windows (PowerShell):
#     cd $HOME
#     git clone https://github.com/once-ere/Dirac_claude.git
#     py -3 -m venv "$HOME\dirac-book-env"

#     python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
#
# STEP 4. IN EVERY NEW TERMINAL: ACTIVATE THE ENVIRONMENT AND GO INTO THE REPOSITORY
# FOLDER.
#
# Every later step starts in the repository folder with the environment active. Run these
# lines whenever you open a new terminal (they do no harm if the environment is already
# active):
#
# Windows (PowerShell):
#     Set-ExecutionPolicy -ExecutionPolicy RemoteSigned -Scope Process -Force
#     & "$HOME\dirac-book-env\Scripts\Activate.ps1"
#     cd "$HOME\Dirac_claude"
#
# macOS (zsh) and Linux (bash):
#     source ~/dirac-book-env/bin/activate
#     cd ~/Dirac_claude
#
# STEP 5. RUN THE NOTEBOOK IN JUPYTERLAB.
#
# In the repository folder, with the environment active, run these two lines (the first
# one goes into the folder of the notebooks):
#
# Windows, macOS and Linux:
#     cd Revision/textbook/notebooks
#     jupyter lab 15c_adiabaticity.ipynb
#
# JupyterLab opens in your web browser and shows the notebook (if no browser window
# opens, copy the address that starts with http://localhost:8888/lab from the terminal
# into the address bar of your browser). The name at the top right of the notebook must
# read Python 3 (ipykernel). Choose the menu Run > Run All Cells. While a cell runs, the
# label to its left shows [*]; when it has finished, the label shows a number. The
# notebook has finished when the last code cell shows a number; this takes about 15
# seconds on a typical laptop. Scroll to the end and compare the last printed lines with
# the lines in the step "What the notebook writes and what you must see" below. To keep
# the results, save the notebook (menu File > Save Notebook). To stop JupyterLab, choose
# the menu File > Shut Down, or press Ctrl+C twice in the terminal.
#
# STEP 6. OR RUN THE NOTEBOOK WITHOUT A BROWSER (HEADLESS).
#
# In the repository folder, with the environment active, run:
#
# Windows, macOS and Linux:
#     cd Revision/textbook/notebooks
```

```
#     jupyter nbconvert --to notebook --execute --inplace 15c_adiabaticity.ipynb
#
# This runs every cell from the top to the bottom and saves the results into the notebook
# file. A failed check stops it with an error message that contains AssertionError and
# the name of the check. If the command ends with a line that starts with [NbConvertApp]
# Writing and shows no error, every check passed; open the notebook with jupyter lab
# 15c_adiabaticity.ipynb (in the same folder, without running the cells again) to read
# the printed lines and see the figures.
#
# STEP 7. WHAT THE NOTEBOOK WRITES AND WHAT YOU MUST SEE.
#
# The notebook writes (or overwrites) these files:
#
# - Revision/textbook/figures/15c.captions.json
# - Revision/textbook/figures/15c_1_transition_orbitals.png
# - Revision/textbook/figures/15c_2_q_by_pair.png
# - Revision/textbook/figures/15c_3_q_history.png
# - Revision/textbook/figures/15c_4_hellmann_feynman.png
# - Revision/textbook/figures/15c_5_fermi_crossing.png
# - Revision/textbook/figures/15c_6_q_map.png
#
# It changes no other file of the repository; running it headless or saving it in
# JupyterLab also rewrites the notebook file itself. It does not use the internet while
# it runs. The files it writes are the same files that are stored in the repository (on
# another computer a figure may differ in a few bytes, which is harmless). To get the
# stored versions back, run this command in the repository folder (it also undoes every
# change you made yourself in the folder Revision/textbook):
#
# Windows, macOS and Linux:
#     git checkout -- Revision/textbook
#
# Every check of the notebook prints a line that starts with PASS. At the end of the
# notebook (the output of its last code cell) you must see exactly these lines:
#
#     PASS every figure file of this notebook exists
#     ALL 12 CHECKS PASSED (notebook 15c)
#
# and the notebook must show 6 figures below the cells that draw them.
#
# STEP 8. IF SOMETHING GOES WRONG.
#
# - "ModuleNotFoundError: No module named ..." in the notebook: JupyterLab was started
#   without the environment. Stop it (menu File > Shut Down), do Step 4, and start it
#   again. If the error remains, another Python installation has registered its own
#   kernel called python3; with the environment active, run the following command and
#   start JupyterLab again:
#     python -m ipykernel install --user --name python3
# - "FileNotFoundError: The repository folder was not found": the notebook was opened
#   from a copy outside the repository. Open the file
#   Revision/textbook/notebooks/15c_adiabaticity.ipynb inside the folder Dirac_claude.
# - "fatal: destination path 'Dirac_claude' already exists" in Step 3: the repository was
#   downloaded before; skip the line with git clone.
# - Windows: "running scripts is disabled on this system": run the line with
#   Set-ExecutionPolicy and then the activation line again. "py is not recognized": use
```

```
#   python instead of py -3; "python is not recognized": install Python again and tick
#   "Add python.exe to PATH".
# - Linux: "ensurepip is not available" when the environment is created: run sudo apt
#   install python3-venv and repeat Step 3.
# - "jupyter is not recognized" or "command not found: jupyter": the environment is not
#   active; do Step 4. If the environment is active and the message stays, the programs
#   jupyter-lab and jupyter-nbconvert are not in the folders where the terminal looks for
#   programs (python -m jupyter does not help then: it has to find the same programs).
#   Start them through Python itself, in the folder of the notebook: the first command
#   below does what jupyter lab does, the second what the headless command does:
#     python -m jupyterlab 15c_adiabaticity.ipynb
#     python -m nbconvert --execute --inplace 15c_adiabaticity.ipynb
# - Windows: the headless run prints a RuntimeWarning that mentions the "Proactor event
#   loop" and zmq: this is a message of the package pyzmq, not an error; the run
#   continues normally.
# - A red box with "Matplotlib is building the font cache; this may take a moment." in
#   the first run after the installation: this is a message, not an error; the run
#   continues and the message does not come again.
# - An AssertionError names a check that failed: choose the menu Kernel > Restart Kernel
#   and Run All Cells; if it fails again, install the packages again with the pip
#   commands of Step 3, because a different package version can change the last digits of
#   a result.
#
# ------------------------------------------------------------------------------------

## 3. The words used in this notebook

- **Instantaneous (adiabatic) state**: the ground state of the Hamiltonian
  $h(a_{4,0})$ of one instant of the history (one slice $a_{4,0}$); the history
  itself keeps moving, with 3-space inflating and the extra times deflating.
- **Adiabatic**: a change of the Hamiltonian slow enough that a system in an
  eigenstate stays in the eigenstate that continues it (the adiabatic theorem).
- **Transition**: a jump of a particle from an occupied level $n$ to an empty level
  $m$; its **amplitude** is a number whose square is the probability of the jump.
- **Matrix element** $\langle n|X|m\rangle$: for orbitals $\chi_n = (a_n, i b_n)$
```

```
  the integral $\int \chi_n^\dagger X \chi_m\,dy$; for $X = \sigma_3$ it is
  $\int (a_n a_m - b_n b_m)\,dy$.
- **Sector**: the shell $n_2$, the block type $j$ and the brane parity. The exact
  evolution conserves all three, so transitions happen only inside a sector.
- **Adiabaticity measure** $Q_{nm} = A H |\langle n|\partial_a h|m\rangle| /
  (\varepsilon_n - \varepsilon_m)^2$: the first-order amplitude of the jump
  $n \to m$; $Q_{max}$ is the largest over all allowed pairs.
- **Hellmann-Feynman theorem**: the derivative of a level with respect to a
  parameter equals the matrix element of the derivative of the Hamiltonian.
- **Aufbau**: filling the lowest levels with the $N$ particles. **Fermi-level
  crossing**: an empty level comes down below an occupied one along the history,
  so the aufbau filling changes. **Adiabatically continued state**: the state
  that keeps the occupations of the first slice.
- **Open shell**: a degenerate group of levels only partly filled.
- **Heat map**: a table of numbers drawn as coloured squares.
```

Text cell:

```
## 4. The physical and mathematical situation

In the author's metric 3-space $x_1, x_2, x_3$ inflates with $e^{a_4}$ and the three
extra times $x_5, x_6, x_7$ deflate with $e^{-a_4}$; the history is $a_4 = A H x_4$
with $A = 1$, a PRESCRIBED BACKGROUND (Revision record ks-theory.json,
adiabaticity.historyStatus). In the hidden coordinate $y$ the Kohn-Sham orbitals of a
sector obey exactly (ks-theory.json, adiabaticity.exactEvolution)

$$i\,\frac{\partial \chi}{\partial x_4} = h(a_4(x_4))\,\chi, \qquad
h_j = j\left[-i\sigma_1 \frac{d}{dy} + M\sigma_2 + \kappa k \sigma_3\right] + v,
\qquad \kappa = e^{-Hy - a_4}.$$

**Where $Q$ comes from.** Write $\chi = \sum_m c_m(x_4)\,e^{-i\theta_m}\,\phi_m$ with
the instantaneous orbitals $h\phi_m = \varepsilon_m\phi_m$ and the phases
$\theta_m = \int \varepsilon_m\,dx_4$. Inserting into the equation and projecting
on $\phi_m$ gives, line by line: (1) the left side gives
$i\dot c_m + \varepsilon_m c_m + i\sum_n c_n e^{i(\theta_m - \theta_n)}\langle
m|\dot\phi_n\rangle$ (product rule; the dot is $d/dx_4$); (2) the right side gives
$\varepsilon_m c_m$; (3) so $\dot c_m = -\sum_n c_n e^{i(\theta_m-\theta_n)}\langle
m|\dot\phi_n\rangle$. (4) Differentiating $h\phi_n = \varepsilon_n\phi_n$ and
projecting on $\phi_m$ ($m \ne n$) gives $\langle m|\dot\phi_n\rangle = \dot a_4
\langle m|\partial_a h|n\rangle/(\varepsilon_n - \varepsilon_m)$. (5) Starting from
$c_n = 1$, integrating (3) over a time in which the phase $e^{i(\varepsilon_m -
\varepsilon_n)x_4}$ turns many times gives an amplitude of size
$|\langle m|\dot\phi_n\rangle|/|\varepsilon_m - \varepsilon_n|$ (the integral of
$e^{i\omega t}$ is $e^{i\omega t}/(i\omega)$), that is, with $\dot a_4 = AH$,

$$Q_{nm} = A H\,\frac{|\langle n|\partial_a h|m\rangle|}{(\varepsilon_n -
\varepsilon_m)^2}, \qquad \text{transition probability} \approx Q_{nm}^2 .$$

The evolution is adiabatic when every $Q_{nm} \ll 1$.

**The derivative of $h$.** Without interaction ($\lambda = 0$) only $\kappa$ depends
on $a_4$, and $\partial\kappa/\partial a_4 = -\kappa$, so
$\partial_a h_j = -j\kappa k\sigma_3$ and
```

```
$\langle n|\partial_a h|m\rangle = -j k e^{-a_{4,0}}\int e^{-Hy}(a_n a_m - b_n b_m)\,dy$.
(With interaction the self-consistent potentials change too; the solver includes
their derivatives. This notebook recomputes the free states $\lambda = 0$ and shows
the recorded values of all states.)

**Hellmann-Feynman.** For $m = n$ the same steps give
$d\varepsilon_n/da_4 = \langle n|\partial_a h|n\rangle$, and the energy of the free
gas, $E = \sum g f\varepsilon$, changes by $dE/da_4 = \sum g f\langle n|\partial_a
h|n\rangle$.

The non-adiabatic (time-dependent) problem itself is OPEN; $Q$ is a first-order
estimate. Units $H = m = 1$, $L = 3$, $\Delta k = 0.25$.
```

Text cell:

```
## 5. The solver's shooting method in Python

The next cell defines the solver's method for the free problem ($M = m$, $v = 0$):
the grid of $G = 900$ RK4 steps on $[-3, 0]$ with its fine grid of step ends and
midpoints, `shoot` (integrate the block equation from the tip, where $b = 0$, to the
brane, and follow the Pruefer angle $\theta = \mathrm{atan2}(b, a)$; the phase
$\Phi = j\theta(0)$ increases with $\varepsilon$ and equals $l\pi$ (even parity) or
$\pi/2 + l\pi$ (odd parity) at the level with label $l$; `shoot` also returns the
derivative $d\Phi/d\varepsilon = \int r^2 dy/r(0)^2$, $r^2 = a^2 + b^2$, with the
integral by the trapezoid rule on the step ends, as in the solver), `find_level`
(the solver's Newton method inside a bracket for $\Phi(\varepsilon) = $ target: walk
with doubling steps until the target is bracketed, then Newton steps, with bisection
whenever a Newton step leaves the bracket or the previous step did not halve the
error; stop when the bracket or a Newton step is below $10^{-13}$), and `orbital`
(the normalised orbital on the fine grid, with cubic Hermite midpoints). The
comments say what each line does.
```

## 6. The levels of the record, solved again

The next cell reads the level table of a free ground state from the record (for
example ‘ground/levels/N136_lam0_a00.csv‘: for each level its shell $n_2$, the
number $r_3$ of momentum vectors in the shell, $k$, $j$, the parity, the label $l$,
the energy and the occupation $f$), keeps the sectors that contain an occupied
level (only there can a particle jump), and solves every level of these sectors
again in Python. Each energy must agree with the solver’s to $10^{-12}$.
```

## 7. The pair of levels with the largest Q

For $N = 136$ at $a_{4,0} = 0$ the record names the pair with the largest $Q$: from
the brane-band level of the shell $n_2 = 4$ ($k = 0.5$, the highest occupied shell,
label 0) to the first bulk level of the same sector (label 1). The next cell draws
the two orbitals and the integrand $\kappa k(a_n a_m - b_n b_m)$ of their matrix
element: the band orbital is bound to the brane, the bulk orbital oscillates
across the interval, so their overlap partly cancels, and the energy difference
($2.05\,m$) is large.
```

In [4]:

```
sector = (4, 1, "even")

## 10. The Hellmann-Feynman theorem and the energy derivative

The next cell takes the occupied brane-band levels of the free state $N = 688$ at
$a_{4,0} = 1$ (shells $n_2 = 1$ to $11$), computes each level also at
$a_{4,0} \pm \delta$ and $\pm 2\delta$ with $\delta = 0.002$ (the solver's step),
forms the **Richardson** combination of the two central differences,
$\tfrac{1}{3}[4 D(\delta) - D(2\delta)]$ with $D(s) = [\varepsilon(a+s) -
\varepsilon(a-s)]/(2s)$ (it removes the error proportional to $\delta^2$), and
compares with the matrix element $\langle n|\partial_a h|n\rangle$. Then it adds up
$dE/da_4 = \sum g f \langle n|\partial_a h|n\rangle$ over all occupied levels,
with the degeneracy $g = 4 r_3(n_2)$, and compares with the derivative the solver
obtained by finite differences of $E$ (column 'dE_da4_finite_difference').
```

## 11. When the Fermi level is crossed

Adiabatic evolution keeps the occupation of every level. If an empty level comes
down below an occupied one along the history (a **Fermi-level crossing**), the
instantaneous ground state fills the new lower level, but the adiabatically
evolving gas cannot get there: the two levels lie in different sectors, and the
exact evolution never moves a particle between sectors. The canonical matrix has no
such crossing (the record file ‘adiabatic/fermi-level-crossings.csv‘). The record’s
demonstration uses $N = 696 = 688 + 8$: at $a_{4,0} = 0$ the eight extra particles
sit in the odd bulk level at $k = 0$ ($\varepsilon = 1.2923$, which does not move),
while the brane band of the shell $n_2 = 12$ ($k = 0.25\sqrt{12} = 0.866$, 32
orbitals) lies above it and comes down along the history. The next cell computes
both levels, finds the slice where they cross by bisection, and computes the
energy by which the adiabatically continued state lies above the instantaneous
ground state, $8\,(\varepsilon_{odd} - \varepsilon_{12})$ (the eight particles of
the $k = 0$ level would sit in the band level instead), at the five slices.
```

In [9]:

```

```

Text cell:

```
## 14. What this notebook showed

- The adiabaticity measure $Q_{nm} = AH|\langle n|\partial_a h|m\rangle|/
  (\varepsilon_n - \varepsilon_m)^2$ is the first-order amplitude of a jump between
  instantaneous levels of one sector; its derivation needs only the product rule and
  the integral of a rotating phase.
- Recomputed in plain Python, every level, the largest $Q$, its pair, its energy
  difference and its matrix element of the free states agree with the Rust
  solver's record (COMPUTED).
- $Q_{max} \le 0.0935$ over the whole canonical matrix (transition probability
  below $0.009$) and it decreases along the history: the instantaneous states are
  followed adiabatically, within the sectors, to a good approximation.
- The Hellmann-Feynman theorem holds, and the energy falls along the history at the
  rate $\sum g f\langle n|\partial_a h|n\rangle$.
- When a level crosses the Fermi level (the demonstration $N = 696$), the
  instantaneous ground state is not the state that the evolution reaches: there the
  instantaneous picture fails, by $3.66$ to $8.62\,m$ in energy. The full
  time-dependent problem is OPEN.
```

15.25 Line-by-line walk-through of Notebook 15c

The notebook has 11 code cells, In [1] to In [11]; the complete cells are printed in Section 15.24.

In [1], the set-up cell. It is the set-up cell of Notebook 15e, explained line by line in Section 15.9, with the run instructions of this notebook (Section 15.23) in its comments and `NOTEBOOK_ID = "15c"`.

In [2], the solver's method for the free problem.

```
import csv  # reads the tables (CSV files) of the Revision record
import math  # exp, sqrt, atan2, pi for single numbers

import numpy as np  # arrays of numbers

L, STEPS = 3.0, 900  # tip cutoff and number of RK4 steps (the solver's values)
POINTS = 2 * STEPS + 1  # step ends and midpoints
STEP = L / STEPS
Y = np.array([-L * ((POINTS - 1 - f) / (POINTS - 1)) for f in range(POINTS)])
EW_LIST = [math.exp(-y) for y in Y.tolist()]  # e^{-Hy} with H = 1, as the solver
EW = np.array(EW_LIST)
```

The imports; $L = 3$ and $G = 900$ steps; the 1801 fine points `Y` (the formula of Notebook 15e, Section 15.9 In [2]); and the factor e^{-Hy} at every fine point, once as a list (fast for single numbers in the loop) and once as an array.

```
SIMPSON = np.full(POINTS, 2.0 * STEP / 6.0)  # Simpson weights on the fine grid
SIMPSON[1::2] = 4.0 * STEP / 6.0
SIMPSON[0] = SIMPSON[-1] = STEP / 6.0
PALETTE = ["#2a78d6", "#eb6834", "#1baf7a", "#eda100", "#e87ba4", "#008300",
           "#4a3aa7", "#e34948"]  # the colours of the figures, in a fixed order
```

The Simpson weights $\frac{h}{6}$ times $1, 4, 2, 4, \ldots, 4, 1$ on the fine grid (Section 15.3), and the colours.

```
def shoot(eps, k, j, a4, store=False):
    kk = k * math.exp(-a4)
    a, b, theta, raw, area, r2_prev = 1.0, 0.0, 0.0, 0.0, 0.0, 1.0
    je = j * eps  # j (eps - v) with v = 0
    nodes = [(a, b)] if store else None
```

The free version of `shoot` of Notebook 15e: the mass is 1 and $v = 0$ everywhere, so they need not be passed. The start values are those of Section 15.9 (In [3]), and `je` is $j\varepsilon$.

```
    for i in range(STEPS):
        k0 = kk * EW_LIST[2 * i]  # kappa k at the start of the step
        k1 = kk * EW_LIST[2 * i + 1]  # at its midpoint
        k2 = kk * EW_LIST[2 * i + 2]  # at its end
        p1a, p1b = a - (k0 + je) * b, (je - k0) * a - b  # (a', b') with M = 1
        aa, bb = a + 0.5 * STEP * p1a, b + 0.5 * STEP * p1b
        p2a, p2b = aa - (k1 + je) * bb, (je - k1) * aa - bb
        aa, bb = a + 0.5 * STEP * p2a, b + 0.5 * STEP * p2b
        p3a, p3b = aa - (k1 + je) * bb, (je - k1) * aa - bb
        aa, bb = a + STEP * p3a, b + STEP * p3b
        p4a, p4b = aa - (k2 + je) * bb, (je - k2) * aa - bb
        a += STEP / 6.0 * (p1a + 2.0 * p2a + 2.0 * p3a + p4a)
        b += STEP / 6.0 * (p1b + 2.0 * p2b + 2.0 * p3b + p4b)
```

The RK4 step written out without the helper `rhs`: κk at the start, the middle and the end of the step; the four slopes (a', b') of the block equation with $M = 1$, each at the prediction made with the previous slope (`aa`, `bb`); and the weighted average $\frac{h}{6}(k_1 + 2k_2 + 2k_3 + k_4)$.

```
        new = math.atan2(b, a)  # the Pruefer angle, followed continuously:
        change = new - raw  # bring the change of angle into (-pi, pi]
        if change > math.pi:
            change -= 2.0 * math.pi
        elif change <= -math.pi:
            change += 2.0 * math.pi
        theta, raw = theta + change, new
        r2 = a * a + b * b
        area, r2_prev = area + 0.5 * STEP * (r2_prev + r2), r2  # trapezoid rule
        if store:
            nodes.append((a, b))
    return j * theta, area / r2_prev, nodes  # Phi and dPhi/deps = int r^2 / r(0)^2
```

The Pruefer angle followed continuously, the trapezoid sum of r^2, the stored values, and the result $(\Phi, d\Phi/d\varepsilon, \text{nodes})$, as in Section 15.9.

```
def find_level(k, j, parity, label, a4, guess, tol=1e-13):
    target = label * math.pi + (0.0 if parity == "even" else 0.5 * math.pi)
    e = guess
    g, d = shoot(e, k, j, a4)[:2]
    g -= target
    if g == 0.0:
        return e
    step = min(max(abs(g / d) * 1.2, 1e-4), 2.0)  # the first trial step
```

`find_level` is the safeguarded Newton method of Section 15.9 (In [5]) for the free problem: the target, the value $g = \Phi - t_l$ and the derivative d at the guess (`[:2]` keeps the first two results of `shoot`), and the first trial step.

```
    if g < 0:  # Phi too small: walk up with doubling steps until Phi >= target
        lo = e
        while True:
            trial = lo + step
            gt, dt = shoot(trial, k, j, a4)[:2]
            gt -= target
            if gt >= 0:
                hi = trial  # [lo, hi] brackets the level
                if abs(gt) < abs(g):
                    e, g, d = trial, gt, dt  # keep the better end for Newton
                break
            lo, e, g, d = trial, trial, gt, dt
            step *= 2.0
    else:  # Phi too large: walk down until Phi <= target
        hi = e
        while True:
            trial = hi - step
            gt, dt = shoot(trial, k, j, a4)[:2]
            gt -= target
            if gt <= 0:
                lo = trial
                if abs(gt) < abs(g):
```

```
                e, g, d = trial, gt, dt
            break
        hi, e, g, d = trial, trial, gt, dt
        step *= 2.0
```

The walk with doubling steps up or down until the target is bracketed, exactly as in Notebook 15e.

```
    previous = math.inf
    while hi - lo > tol and g != 0.0:
        new = e - g / d  # Newton step, or bisection if it leaves the bracket
        bisect = not lo < new < hi or abs(g) > 0.5 * previous
        if bisect:
            new = 0.5 * (lo + hi)
        previous = abs(g)
        moved = abs(new - e)
        e = new
        g, d = shoot(e, k, j, a4)[:2]
        g -= target
        if g < 0:
            lo = e
        elif g > 0:
            hi = e
        if moved <= tol and not bisect:
            break  # a Newton step that moves less than tol: converged
    return e
```

The refinement by Newton steps with bisection as the safeguard, written as a `while` loop that runs as long as the bracket is longer than the tolerance and the target is not hit exactly; otherwise as in Notebook 15e.

```
def orbital(eps, k, j, a4):
    nodes = np.array(shoot(eps, k, j, a4, store=True)[2])
    kap = k * math.exp(-a4) * EW[0::2]
    a_n, b_n = nodes[:, 0], nodes[:, 1]
    da = a_n - (kap + j * eps) * b_n  # derivatives at the step ends
    db = (j * eps - kap) * a_n - b_n
    a = np.zeros(POINTS)
    b = np.zeros(POINTS)
    a[0::2], b[0::2] = a_n, b_n
    a[1::2] = 0.5 * (a_n[:-1] + a_n[1:]) + STEP / 8.0 * (da[:-1] - da[1:])
    b[1::2] = 0.5 * (b_n[:-1] + b_n[1:]) + STEP / 8.0 * (db[:-1] - db[1:])
    norm = math.sqrt(float(np.sum(SIMPSON * (a * a + b * b))))
    return a / norm, b / norm
```

The normalised orbital on the fine grid, as in Section 15.9 (In [7]): the stored step-end values become a two-column array (`nodes[:, 0]` is its first column, a; `nodes[:, 1]` the second, b), the derivatives come from the block equation, the midpoints from the Hermite formula, and Simpson's rule normalises.

```
def da_h(k, j, a4, first, second):
    s3 = first[0] * second[0] - first[1] * second[1]
    return -j * k * math.exp(-a4) * float(np.sum(SIMPSON * EW * s3))
```

`da_h` is the matrix element $\langle n|\partial_a h|m\rangle = -j\,k\,e^{-a_{4,0}}\int e^{-Hy}(a_n a_m - b_n b_m)\,dy$ of Section 15.21, with the integral by Simpson's rule; `first` and `second` are orbitals, each a pair (a, b) of arrays. The cell defines functions only and prints nothing.

In [3], the levels of the record solved again.

```
LEVELS = "Revision/kohn_sham/results/ground/levels"
SLICES = [0.0, 0.5, 1.0, 1.5, 2.0]

def state_id(n, a4, tag="lam0"):
    return f"N{n}_{tag}_a{round(10 * a4):02d}"
```

The folder of the level tables, the five slices, and the state names as in Notebook 15a (here the coupling tag comes last, with the default `lam0`).

```
def solve_state(n, a4):
    rows = list(csv.DictReader(open(repository_file(f"{LEVELS}/{state_id(n, a4)}.csv"),
                                    newline="", encoding="utf-8")))
    sectors = {}
    for row in rows:
        sector = (int(row["n2"]), int(row["j"]), row["parity"])
        sectors.setdefault(sector, []).append(row)
```

`solve_state` reads the level table of a free state into a list of rows and groups the rows by sector: `setdefault(sector, [])` returns the list of that sector, creating an empty one the first time, and the row is appended to it.

```
    solved, worst = {}, 0.0
    for sector, members in sectors.items():
        if all(float(row["f"]) < 0.5 for row in members):
            continue  # no particle in this sector: no transition starts here
        solved[sector] = {}
        for row in members:
            k, eps_rec = float(row["k"]), float(row["eps"])
            eps = find_level(k, sector[1], sector[2], int(row["label"]), a4, eps_rec)
            worst = max(worst, abs(eps - eps_rec))
            solved[sector][int(row["label"])] = (
                eps, float(row["f"]), k, int(row["r3"]), orbital(eps, k, sector[1], a4))
    return solved, worst
```

Sectors without an occupied level are skipped: no transition can start there. For every level of the other sectors the energy is found again in Python, starting from the recorded value, and stored with its occupation, momentum, number of directions r_3 and orbital, under its sector and label; `worst` is the largest difference to the record.

```
states = {}
worst_level = 0.0
for n in (136, 688):
```

```
    for a4 in SLICES:
        states[(n, a4)], worst = solve_state(n, a4)
        worst_level = max(worst_level, worst)
count = sum(len(levels) for state in states.values() for levels in state.values())
report("levels solved again (10 states)", count)
report("largest |eps(Python) - eps(solver)|", f"{worst_level:.1e}")
check(worst_level < 1e-12, "every level equals the solver's level within 1e-12",
      record=f"{LEVELS}/N136_lam0_a*.csv and N688_lam0_a*.csv, column eps")
```

The ten free states $N = 136,688$ at the five slices are solved. Out [3]: 270 levels, the largest difference to the solver 9.3×10^{-14}, PASS.

In [4], the pair with the largest Q.

```
sector = (4, 1, "even")
band = states[(136, 0.0)][sector][0]  # (eps, f, k, r3, (a, b)) of label 0
bulk = states[(136, 0.0)][sector][1]  # label 1
k = band[2]
integrand = k * EW * (band[4][0] * bulk[4][0] - band[4][1] * bulk[4][1])
```

For $N = 136$ at $a_{4,0} = 0$ the record names the pair `4:+1:even:0 -> 4:+1:even:1`: in the sector $n_2 = 4$ ($k = 0.5$), $j = +1$, even, the occupied band level (label 0) and the first empty bulk level (label 1). `band[4]` is the orbital (a, b) of the band level; `integrand` is $\kappa k\,(a_n a_m - b_n b_m)$ at $a_{4,0} = 0$.

```
fig, (left, right) = plt.subplots(1, 2, figsize=(10.0, 4.0), layout="constrained")
left.plot(Y, band[4][0], color=PALETTE[0], lw=2.0, label="band: $a$")
left.plot(Y, band[4][1], color=PALETTE[0], lw=1.5, ls="--", label="band: $b$")
left.plot(Y, bulk[4][0], color=PALETTE[1], lw=2.0, label="bulk: $a$")
left.plot(Y, bulk[4][1], color=PALETTE[1], lw=1.5, ls="--", label="bulk: $b$")
left.set_xlabel("hidden coordinate $y$")
left.set_ylabel("orbital (normalised)")
left.set_title(f"$n_2 = 4$: band $\\varepsilon = {band[0]:.4f}$, "
               f"bulk $\\varepsilon = {bulk[0]:.4f}$", fontsize=10)
left.legend(fontsize=8)
```

The left panel draws both orbitals (a solid, b dashed), with their energies in the title.

```
right.plot(Y, integrand, color=PALETTE[2], lw=2.0)
right.fill_between(Y, integrand, color=PALETTE[2], alpha=0.25)
right.set_xlabel("hidden coordinate $y$")
right.set_ylabel("$\\kappa k\\,(a_n a_m - b_n b_m)$ (units of $m^2$)")
right.set_title("Integrand of the matrix element")
save_figure(fig, "transition_orbitals",
            "Left: the orbitals (components $a$ solid, $b$ dashed; vertical axis, "
...)
element = abs(da_h(k, 1, 0.0, band[4], bulk[4]))
report("|<band| d_a h |bulk>| and Q for N = 136, a4,0 = 0",
       f"{element:.13f}, {element / (band[0] - bulk[0]) ** 2:.13f}")
```

The right panel draws the integrand and shades the area between it and zero (`fill_between`), whose signed size is the matrix element; then Figure 15c.1. Out [4]: $|\langle n|\partial_a h|m\rangle| = 0.3588612$ and

$Q = 0.3588612/(2.052930)^2 = 0.0851488$. The band orbital sits at the brane and the bulk orbital oscillates, so the integrand changes sign and partly cancels; together with the large energy difference this keeps Q small.

In [5], Q for every allowed pair.

```
ADIABATIC = "Revision/kohn_sham/results/adiabatic/adiabaticity.csv"
with open(repository_file(ADIABATIC), newline="", encoding="utf-8") as handle:
    adiabatic = {row["id"]: row for row in csv.DictReader(handle)}

def key_text(sector, label):
    return f"{sector[0]}:{sector[1]:+d}:{sector[2]}:{label}"
```

The record's adiabaticity table is read. `key_text` writes a level as the record writes it, `n2:j:parity:label`; the format `+d` prints the block type with its sign.

```
pairs = {}  # (n, a4) -> list of (Q, n2, label m) for the figure
worst_q, same_pairs = 0.0, True
say("   N  a4,0   Q_max    pair                            delta eps   matrix el.")
for (n, a4), state in states.items():
    best = (0.0, "", 0.0, 0.0)
    pairs[(n, a4)] = []
    for sector, levels in state.items():
        for ln, (en, fn, k, _, on) in levels.items():
            if fn < 0.5:
                continue
            for lm, (em, fm, _, _, om) in levels.items():
                if fm > 0.5:
                    continue
                element = abs(da_h(k, sector[1], a4, on, om))
                q = element / (en - em) ** 2  # A H = 1
                pairs[(n, a4)].append((q, sector[0], lm))
                if q > best[0]:
                    best = (q, f"{key_text(sector, ln)} -> {key_text(sector, lm)}",
                            abs(en - em), element)
```

For each of the ten states and each occupied sector, the two inner loops run over every occupied level n (`fn` its occupation; empty ones are skipped) and every empty level m (occupied ones are skipped) of the same sector. For each pair the matrix element and $Q = |\langle n|\partial_a h|m\rangle|/(\varepsilon_n - \varepsilon_m)^2$ (with $AH = 1$) are computed and stored for the figure, and `best` keeps the largest Q with its pair, energy difference and matrix element.

```
    row = adiabatic[state_id(n, a4)]
    for value, column in ((best[0], "Q_max"), (best[2], "Q_max_delta_eps"),
                          (best[3], "Q_max_matrix_element")):
        worst_q = max(worst_q, abs(value / float(row[column]) - 1.0))
    same_pairs = same_pairs and best[1] == row["Q_max_pair"]
    say(f"{n:4d}  {a4:4.1f}  {best[0]:.5f}  {best[1]:28}  {best[2]:9.6f}"
        f"  {best[3]:9.6f}")
```

Still inside the loop over the states: the largest Q, its energy difference and its matrix element are compared with the record, the pair's name too, and a table row is printed.

```
report("largest relative difference to the record", f"{worst_q:.1e}")
check(worst_q < 1e-9, "Q_max, its energy difference and matrix element reproduced",
      record=f"{ADIABATIC}, columns Q_max, Q_max_delta_eps, Q_max_matrix_element")
check(same_pairs, "the pair with the largest Q is the recorded pair",
      record=f"{ADIABATIC}, column Q_max_pair")
```

Out [5] shows the table: Q_{max} falls from 0.08515 to 0.03839 for $N = 136$ and from 0.09345 to 0.05289 for $N = 688$ along the history, always for the jump from the band level of the highest occupied shell ($n_2 = 4$, respectively 11) to the bulk level above it in the same sector. The largest relative difference to the record is 6.8×10^{-14}, and the pairs are the recorded ones.

In [6], every pair at the first slice.

```
fig, ax = plt.subplots()
for marker, n in (("o", 136), ("s", 688)):
    for colour, label in zip(PALETTE, (1, 2)):
        points = [(n2, q) for q, n2, lm in pairs[(n, 0.0)] if lm == label]
        ax.plot([p[0] for p in points], [max(p[1], 1e-6) for p in points], marker,
                color=colour, ms=8 if n == 136 else 6,
                markerfacecolor=colour if n == 136 else "white",
                label=f"$N = {n}$, to label {label}")
```

For $N = 136$ (filled circles) and $N = 688$ (open squares) at $a_{4,0} = 0$, the cell draws Q of every pair against the shell of its sector, coloured by the label of the empty level (1 or 2). Values below 10^{-6} (the transitions at $k = 0$, which are exactly zero) are drawn at 10^{-6}, because a logarithmic axis cannot show zero.

```
ax.set_yscale("log")
ax.set_xlabel("shell $n_2$ of the sector ($k = 0.25\\sqrt{n_2}$)")
ax.set_ylabel("$Q_{nm}$ (pure number)")
ax.set_title("Every allowed transition at $a_{4,0} = 0$, $\\lambda = 0$")
ax.legend(fontsize=8)
save_figure(fig, "q_by_pair",
            "The adiabaticity measure $Q_{nm}$ (vertical axis, logarithmic, pure "
...)
largest = max(q for values in pairs.values() for q, _, _ in values)
report("largest Q of all free pairs (10 states)", f"{largest:.5f}")
check(largest < 0.1, "every Q of the free states is below 0.1")
```

Figure 15c.2, and the largest Q over all pairs of the ten states: 0.09345 (Out [6]), below 0.1. In the figure the jump to the label 1 dominates in every shell and grows with n_2, because the matrix element is proportional to k.

In [7], Q_{max} of the whole matrix.

```
fig, (left, right) = plt.subplots(1, 2, figsize=(10.0, 4.0), layout="constrained")
tags = [("lam0", "$0$"), ("lamp1", "$+\\lambda_1$"), ("lamm1", "$-\\lambda_1$"),
```

```
        ("lamp2", "$+\\lambda_2$"), ("lamm2", "$-\\lambda_2$")]
record_max = 0.0
for style, n in (("-", 136), ("--", 688)):
    for colour, (tag, label) in zip(PALETTE, tags):
        values = [float(adiabatic[state_id(n, a4, tag)]["Q_max"]) for a4 in SLICES]
        record_max = max(record_max, max(values))
        left.plot(SLICES, values, style, color=colour, lw=1.5, marker="o", ms=4,
                  label=f"$N = {n}$, $\\lambda = $ {label}")
        right.plot(SLICES, [v * v for v in values], style, color=colour, lw=1.5,
                   marker="o", ms=4)
```

For $N = 136$ (solid) and 688 (dashed) and the five couplings the recorded Q_{max} at the five slices is drawn on the left and its square, the transition probability, on the right; `record_max` keeps the largest value.

```
    mine = [max(q for q, _, _ in pairs[(n, a4)]) for a4 in SLICES]
    left.plot(SLICES, mine, "x", color="black", ms=10, mew=2)
left.plot([], [], "x", color="black", ms=10, mew=2, label="this notebook")
left.set_yscale("log")
left.set_xlabel("slice $a_{4,0}$")
left.set_ylabel("$Q_{max}$")
left.set_title("Largest $Q$ (record)")
left.legend(fontsize=7, ncol=2)
right.set_yscale("log")
right.set_xlabel("slice $a_{4,0}$")
right.set_ylabel("$Q_{max}^2$")
right.set_title("Transition probability estimate")
save_figure(fig, "q_history",
            "Left: the largest adiabaticity measure $Q_{max}$ (vertical axis, "
...)
```

The values recomputed in this notebook for $\lambda = 0$ are drawn as black crosses (`mew` is the width of the cross lines), then the legend, axes and Figure 15c.3.

```
n8_zero = all(float(adiabatic[state_id(8, a4, tag)]["Q_max"]) == 0.0
              for a4 in SLICES for tag, _ in tags)
report("largest Q_max of the whole matrix (record)", f"{record_max:.4f}")
check(record_max <= 0.0935 and n8_zero,
      "Q_max <= 0.0935 over the matrix, and Q = 0 exactly for N = 8",
      record=f"{ADIABATIC}, column Q_max")
falling = all(max(q for q, _, _ in pairs[(n, SLICES[i + 1])])
              < max(q for q, _, _ in pairs[(n, SLICES[i])])
              for n in (136, 688) for i in range(4))
check(falling, "Q_max of the free states falls from slice to slice")
```

Out [7]: the largest Q_{max} of the matrix is 0.0935, every Q of $N = 8$ is exactly zero (only $k = 0$ is occupied, where $\partial_a h = 0$), and Q_{max} of the free states falls from slice to slice.

In [8], the Hellmann-Feynman theorem.

```
DELTA = 2e-3
a0 = 1.0
```

```
state = states[(688, a0)]
shells, finite, element = [], [], []
for sector, levels in sorted(state.items()):
    if sector[0] == 0:
        continue  # the zero modes do not depend on a4,0
    eps, f, k, r3, orb = levels[0]  # the occupied brane-band level (label 0)
    near = {s: find_level(k, sector[1], sector[2], 0, a0 + s, eps)
            for s in (DELTA, -DELTA, 2 * DELTA, -2 * DELTA)}
```

For the free state $N = 688$ at $a_{4,0} = 1$ the cell visits the occupied sectors in sorted order, skips the shell $n_2 = 0$, and takes the occupied band level (label 0) of each shell; it solves this level again at the four slices 1 ± 0.002 and 1 ± 0.004.

```
    d1 = (near[DELTA] - near[-DELTA]) / (2 * DELTA)
    d2 = (near[2 * DELTA] - near[-2 * DELTA]) / (4 * DELTA)
    shells.append(k)
    finite.append((4.0 * d1 - d2) / 3.0)
    element.append(da_h(k, sector[1], a0, orb, orb))
hf_dev = max(abs(a - b) for a, b in zip(finite, element))
```

`d1` and `d2` are the central differences $D(\delta)$ and $D(2\delta)$, $D(s) = [\varepsilon(a+s) - \varepsilon(a-s)]/(2s)$; their error is proportional to s^2, so the Richardson combination $\frac{1}{3}(4D(\delta) - D(2\delta))$ removes it (as in Section 15.9, In [9]). `element` is the diagonal matrix element $\langle n|\partial_a h|n\rangle$, and `hf_dev` the largest difference between the two.

```
de_da = sum(4.0 * levels[l][3] * levels[l][1] * da_h(levels[l][2], sector[1], a0,
                                                     levels[l][4], levels[l][4])
            for sector, levels in state.items() for l in levels)
recorded = float(adiabatic[state_id(688, a0)]["dE_da4_finite_difference"])
```

`de_da` is $\sum g f \langle n|\partial_a h|n\rangle$ over all levels of the occupied sectors, with $g = 4r_3$ (`levels[l][3]` is r_3, `levels[l][1]` the occupation, which is 0 for the empty levels); `recorded` is the derivative of E that the solver obtained by finite differences.

```
fig, ax = plt.subplots()
ax.plot(shells, finite, "o", color=PALETTE[0], ms=9, label="finite differences")
ax.plot(shells, element, "x", color=PALETTE[1], ms=10, mew=2,
        label="$\\langle n|\\partial_a h|n\\rangle$")
ax.set_xlabel("3-momentum $k$ of the shell (units of $m$)")
ax.set_ylabel("$d\\varepsilon/da_4$ (units of $m$)")

            "adiabatic_hellmann_feynman")
check(abs(de_da / recorded - 1.0) < 1e-9, "dE/da4 = sum g f <n| d_a h |n>",
      record=f"{ADIABATIC}, N688_lam0_a10, column dE_da4_finite_difference")
```

Figure 15c.4 draws both derivatives of the eleven band levels against their momentum: circles and crosses coincide, and every level falls, faster for larger k. Out [8]: the largest difference is 1.7×10^{-12}, and $dE/da_4 = -253.0160345318$ against the record's -253.0160345309; both checks pass.

In [9], the Fermi-level crossing of $N = 696$.

```
K12 = 0.25 * math.sqrt(12.0)
eps_odd = find_level(0.0, 1, "odd", 0, 0.0, 1.29)  # the k = 0 odd bulk level

def band12(a4):
    return find_level(K12, 1, "even", 0, a4, 1.9 * K12 * math.exp(-a4))
```

`K12` is the momentum $0.25\sqrt{12} = 0.866$ of the shell $n_2 = 12$; `eps_odd` the odd bulk level at $k = 0$ (it does not depend on the slice); `band12` the band level of the shell 12 at a given slice.

```
lo, hi = 0.0, 0.5  # bisection for band12(a4) = eps_odd
for _ in range(45):
    mid = 0.5 * (lo + hi)
    lo, hi = (mid, hi) if band12(mid) > eps_odd else (lo, mid)
crossing = 0.5 * (lo + hi)
dense = np.linspace(0.0, 2.0, 41)
band_curve = [band12(a) for a in dense]
```

Bisection finds the slice at which the falling band level meets the bulk level: while the band level is still above, the crossing lies later. 45 halvings of the interval from 0 to 0.5 locate it far below the printed digits. `band_curve` is the band level at 41 slices for the figure.

```
with open(repository_file("Revision/kohn_sham/results/adiabatic/crossing-demo.csv"),
          newline="", encoding="utf-8") as handle:
    demo = {float(row["a4"]): row for row in csv.DictReader(handle)}
mine = {a4: max(0.0, 8.0 * (eps_odd - band12(a4))) for a4 in SLICES}
worst_demo = max(abs(mine[a4] - float(demo[a4]["difference"])) for a4 in SLICES)
```

The record's demonstration table is read, filed by slice. Without interaction the adiabatically continued state keeps its eight particles in the bulk level, while the instantaneous aufbau state puts them into the lower band level; the energy difference is therefore $8(\varepsilon_{odd} - \varepsilon_{12})$ after the crossing and 0 before it (`max(0.0, ...)`). `worst_demo` compares this with the record's column `difference`.

```
fig, (left, right) = plt.subplots(1, 2, figsize=(10.0, 4.0), layout="constrained")
left.plot(dense, band_curve, color=PALETTE[0], lw=2.0,
          label="brane band $n_2 = 12$ (32 orbitals)")
left.axhline(eps_odd, color=PALETTE[1], lw=2.0, label="odd bulk level, $k = 0$ (8)")
left.axvline(crossing, color="0.4", ls=":", lw=1.2, label="crossing")
```

```
left.set_xlabel("slice $a_{4,0}$")
left.set_ylabel("level (units of $m$)")
left.set_title("Two levels near the Fermi level, $N = 696$")
left.legend(fontsize=8)
```

The left panel: the band level of the shell 12 (degeneracy $4r_3(12) = 4 \cdot 8 = 32$), the fixed bulk level (8-fold) as a horizontal line, and the crossing as a dotted vertical line (`axvline`).

```
right.plot(SLICES, [float(demo[a]["difference"]) for a in SLICES], "o", color="black",
           ms=9, label="record")
right.plot(SLICES, [mine[a] for a in SLICES], "x", color=PALETTE[0], ms=10, mew=2,
           label="$8(\\varepsilon_{odd} - \\varepsilon_{12})$, this notebook")
right.set_xlabel("slice $a_{4,0}$")
right.set_ylabel("$E_{continued} - E_{aufbau}$ (units of $m$)")
right.set_title("Energy above the instantaneous ground state")
right.legend(fontsize=8)
save_figure(fig, "fermi_crossing",
            "The Fermi-level crossing of the demonstration state $N = 696$ without "
...)
```

The right panel: the recorded energy differences (black dots) and this notebook's (blue crosses) at the five slices; then Figure 15c.5.

```
report("band level n2 = 12 minus the odd level at a4,0 = 0",
       f"{band_curve[0] - eps_odd:.10f}")
report("crossing slice a4,0", f"{crossing:.6f}")
report("largest |8 (eps_odd - eps_12) - recorded difference|", f"{worst_demo:.1e}")
check(0.0 < crossing < 0.5, "the crossing lies between the slices 0 and 0.5",
      record="Revision/kohn_sham/results/adiabatic/crossing-demo.csv, flags at 0 "
             "and 0.5")
check(worst_demo < 1e-9, "the energy differences of the demonstration reproduced",
      record="Revision/kohn_sham/results/adiabatic/crossing-demo.csv, column "
             "difference")
```

Out [9]: at $a_{4,0} = 0$ the band level lies only $0.0032325\,m$ above the bulk level, so the crossing comes almost at once, at $a_{4,0} = 0.002854$; the energy differences agree with the record to 2.0×10^{-11}. Both checks pass.

In [10], the heat map.

```
rows, names = [], []
for n in (8, 136, 688):
    for tag, label in tags:
        rows.append([float(adiabatic[state_id(n, a4, tag)]["Q_max"]) for a4 in SLICES])
        names.append(f"N = {n}, {tag}")
table = np.array(rows)
```

A table of Q_{max} with one row per series (15 rows: three particle numbers times five couplings) and one column per slice, with a name for each row.

```
fig, ax = plt.subplots(figsize=(6.5, 6.0))
image = ax.imshow(table, cmap="Blues", aspect="auto", vmin=0.0, vmax=0.1)
ax.grid(False)  # no grid lines across the coloured squares
ax.set_xticks(range(5), [f"{a:.1f}" for a in SLICES])
ax.set_yticks(range(len(names)), names, fontsize=8)
for i in range(table.shape[0]):
    for jj in range(table.shape[1]):
        ax.text(jj, i, f"{table[i, jj]:.3f}", ha="center", va="center", fontsize=7,
                color="white" if table[i, jj] > 0.06 else "black")
```

`ax.imshow` draws the table as coloured squares, from white (0) to dark blue (0.1); `aspect="auto"` lets the squares fill the drawing area. The ticks are labelled with the slices and the row names, and every square gets its value printed in its middle (`table.shape` is the pair (rows, columns); white letters on the dark squares).

```
ax.set_xlabel("slice $a_{4,0}$")
ax.set_title("$Q_{max}$ of the 75 ground states (record)")
fig.colorbar(image, ax=ax, label="$Q_{max}$")
save_figure(fig, "q_map",
            "Heat map of the largest adiabaticity measure $Q_{max}$ of the 75 ground "
...)
with open(repository_file("Revision/kohn_sham/results/adiabatic/"
                          "fermi-level-crossings.csv"), newline="",
          encoding="utf-8") as handle:
    crossings = list(csv.DictReader(handle))
changed = sum(row["occupied_set_changed"] == "true" for row in crossings)
report("rows of the crossing record / rows with a changed occupied set",
       f"{len(crossings)} / {changed}")
check(len(crossings) == 60 and changed == 0,
      "no Fermi-level crossing in the canonical matrix",
      record="Revision/kohn_sham/results/adiabatic/fermi-level-crossings.csv")
```

A colour scale, Figure 15c.6, and the check that none of the 60 rows of the record's crossing table (15 series, four steps between neighbouring slices) reports a change of the occupied set (Out [10]: 60 / 0).

In [11], the last check.

```
NAMES = ["transition_orbitals", "q_by_pair", "q_history", "hellmann_feynman",
         "fermi_crossing", "q_map"]
missing = [name for number, name in enumerate(NAMES, start=1)
           if not output_file(f"{FIGURE_FOLDER}/15c_{number}_{name}.png").is_file()]
check(missing == [], "every figure file of this notebook exists")
all_checks_passed()
```

As in Notebook 15e (Section 15.9, In [15]), with the six figure names of this notebook in order and the file names `15c_<number>_<name>.png`: the names whose file does not exist are collected, the check requires that list to be empty, and `all_checks_passed()` prints the last line, ALL 12 CHECKS PASSED (notebook 15c).

15.26 The gas at a temperature

Mermin's functional. At a temperature $T > 0$ the particles no longer fill exactly the lowest levels. Mermin's finite-temperature form of Kohn-Sham theory (Chapter 13) occupies each level with the **Fermi-Dirac** probability

$$f(x) = \frac{1}{1 + e^{x}}, \qquad x = \frac{\varepsilon - \mu}{T},$$

where the **chemical potential** μ is fixed by the particle number, $\sum g f = N$. The function f is 1 far below μ, 0 far above, and $\frac{1}{2}$ at $\varepsilon = \mu$; it falls from nearly 1 to nearly 0 over a few T (Figure 15d.5 shows it). A useful identity: $1 - f(x) = f(-x)$, because $1 - \frac{1}{1+e^{x}} = \frac{e^{x}}{1+e^{x}} = \frac{1}{e^{-x}+1}$. The functions of state of the doubled system are (ks-theory.json, thermodynamics):

$$E = \sum g f \varepsilon - 2\,\mathrm{Vol}_7 \int e^{6Hy} e_{int}\, dy, \qquad S = -\sum g\,[f \ln f + (1 - f)\ln(1 - f)],$$

$$F = E - TS, \qquad \Omega = -T \sum g \ln\left(1 + e^{-(\varepsilon-\mu)/T}\right) - 2\,\mathrm{Vol}_7 \int e^{6Hy} e_{int}\, dy = F - \mu N,$$

the energy, the **entropy** (a measure of how many arrangements of the particles the occupations allow), the **free energy** and the **grand potential**. The last equality is Exercise 5. The self-consistent loop is the one of Section 15.5 with the Fermi-Dirac occupations in place of the aufbau. A note on the record: the theory file writes the particle-number condition as $\sum w g f = N$ with $w = \frac{1}{2}$, which contradicts its own densities, energy and grand potential; the solver uses $\sum g f = N$, the particle number of the doubled system, and records the discrepancy (`Revision/kohn_sham/results/parameters.json`, conventions.particleNumber).

The record's thermal states. 135 states: $N = 8,136,688$, the couplings $0, \pm\lambda_1$, the five slices and $T = 0.01, 0.02, 0.05$ (Section 15.2). Their label sets contain every particle level whose free occupation is above 10^{-12} (the thermal window; check thermo_window_cut), and the solver checks $\sum g f = N$ to 3.1×10^{-12} (check thermo_N_conservation), the two forms of Ω (check thermo_grand_potential_two_forms) and the identities $C_V = T\,dS/dT = dE/dT$ and $-dF/dT = S$ with differences between neighbouring temperatures (checks thermo_CV_identity and thermo_entropy_identity).

The heat capacity in closed form. The **heat capacity** $C_V = dE/dT$ at fixed N says how much energy one unit of temperature costs. Without interaction the levels do not depend on T, and C_V has a closed form. With the shorthand $f_i = f(x_i)$, $d_i = \varepsilon_i - \mu$ and $w_i = g_i f_i (1 - f_i)$, line by line:

$$\frac{df}{dx} = -\frac{e^{x}}{(1 + e^{x})^2} = -f(1 - f).$$

Rule: the derivative of $1/(1 + e^{x})$ by the chain rule; then $\frac{e^{x}}{(1+e^{x})^2} = \frac{1}{1+e^{x}} \cdot \frac{e^{x}}{1+e^{x}} = f\,(1 - f)$.

$$\frac{dx_i}{dT} = -\frac{d_i}{T^2} - \frac{1}{T}\frac{d\mu}{dT}.$$

Rule: $x_i = (\varepsilon_i - \mu)/T$ with fixed ε_i; the quotient rule, and μ changes with T because N is fixed.

$$0 = \frac{dN}{dT} = \sum_i g_i \frac{df}{dx}(x_i)\frac{dx_i}{dT} = -\sum_i w_i \frac{dx_i}{dT}, \qquad \frac{d\mu}{dT} = -\frac{\sum_i w_i d_i}{T\sum_i w_i}.$$

Rule: differentiate $\sum g_i f_i = N$; insert the first line; then insert the second line and solve for $d\mu/dT$.

$$C_V = \frac{dE}{dT} = -\sum_i w_i \varepsilon_i \frac{dx_i}{dT} = -\sum_i w_i d_i \frac{dx_i}{dT} = \frac{1}{T^2}\Big[\sum_i w_i d_i^2 - \frac{(\sum_i w_i d_i)^2}{\sum_i w_i}\Big].$$

Rule: differentiate $E = \sum g_i f_i \varepsilon_i$ in the same way; replacing ε_i by $d_i = \varepsilon_i - \mu$ subtracts $\mu \sum w_i\, dx_i/dT$, which is zero by the previous line; then insert the second line and the value of $d\mu/dT$. In the same way $dN/d\mu = \sum_i g_i \frac{df}{dx}(x_i)\cdot(-\frac{1}{T}) = \frac{1}{T}\sum_i w_i$ at fixed T.

$T\,dS/dT = dE/dT$ and $-dF/dT = S$. The entropy of one level is $-g[f\ln f + (1-f)\ln(1-f)]$; its derivative with respect to f is $-g[\ln f + 1 - \ln(1-f) - 1] = g\ln\frac{1-f}{f} = g\,x$, because $\frac{1-f}{f} = e^x$. So, line by line,

$$\frac{dS}{dT} = \sum_i g_i x_i \frac{df}{dx}(x_i)\frac{dx_i}{dT} = -\sum_i w_i x_i \frac{dx_i}{dT} = -\frac{1}{T}\sum_i w_i d_i \frac{dx_i}{dT} = \frac{1}{T}\frac{dE}{dT}.$$

Rule: the chain rule with the derivative just found; $df/dx = -f(1-f)$; $x_i = d_i/T$; and the previous derivation of dE/dT. Hence $C_V = T\,dS/dT$, and $\frac{dF}{dT} = \frac{dE}{dT} - S - T\frac{dS}{dT} = -S$ (the product rule on TS). The solver reports C_V as $T\,dS/dT$, because the entropy is computed from the occupations and is well conditioned, while dE/dT is a difference of nearly equal energies.

The two-level formula for $N = 8$. At $a_{4,0} = 0$ and low temperature only two groups of levels matter for $N = 8$: the eight zero modes at $\varepsilon = 0$ and the 24 orbitals of the first band shell at $\varepsilon = \Delta = 0.4307$ (the gap). The particles that leave the zero modes must enter the band, line by line:

$$8\,(1 - f(-\mu/T)) = 24\,f((\Delta-\mu)/T).$$

Rule: the holes in the zero modes equal the particles in the band, because N is fixed.

$$8\,e^{-\mu/T} = 24\,e^{-(\Delta-\mu)/T}.$$

Rule: $1 - f(x) = f(-x)$, and $f(x) \approx e^{-x}$ for $x \gg 1$; here μ/T and $(\Delta-\mu)/T$ are about 21 and 22.

$$\ln 8 - \frac{\mu}{T} = \ln 24 - \frac{\Delta-\mu}{T}, \qquad \mu = \frac{\Delta}{2} - \frac{T}{2}\ln 3.$$

Rule: take the logarithm of both sides; collect μ on one side ($-2\mu/T = \ln 3 - \Delta/T$, since $\ln 24 - \ln 8 = \ln 3$) and divide by $-2/T$. At $T \to 0$ the chemical potential sits in the middle of the gap; it falls linearly with the slope $-\frac{1}{2}\ln 3$, the logarithm of the ratio of the degeneracies. At $T = 0.01$ the formula gives 0.209873777875, the record 0.209873776387 (Notebook 15d, Out [5]); the difference 1.5×10^{-9} is the size of the neglected terms.

Why μ must be computed with care. Near a closed shell at low temperature almost every level is either full or empty. The direct count $\sum gf - N$ then adds numbers very close to 1 and subtracts

N; in double precision (the computer's numbers, about 16 significant digits) the result is only known to about ϵN, where $\epsilon = 2^{-52} = 2.2 \times 10^{-16}$ is the rounding unit, while the count changes with μ only at the rate $dN/d\mu$. A root of the direct count is therefore uncertain by about $\epsilon N/(dN/d\mu)$. For $N = 8$ at $a_{4,0} = 0$, $T = 0.01$ the record has $dN/d\mu = 1.23 \times 10^{-6}$ (`Revision/kohn_sham/results/thermo/thermodynamics.csv`), so this uncertainty is $2.2 \times 10^{-16} \cdot 8/(1.23 \times 10^{-6}) = 1.4 \times 10^{-9}\, m$, a million times worse than the rounding unit. An earlier version of the solver used the direct count, and the independent cross-check of Chapter 16 found its μ off by $8.3 \times 10^{-10}\, m$ in the state `N8_lamm1_a00_T10` (`Revision/kohn_sham/solver/README.md`, History).

The balance form, line by line. Let $\mathcal{S}$ be the set of the levels that are filled at $T = 0$ and $d = N - \sum_{\mathcal{S}} g$ (zero for a closed shell). Then

$$\sum_i g_i f(x_i) - N = \sum_{i \notin \mathcal{S}} g_i f(x_i) + \sum_{i \in \mathcal{S}} g_i (1 - f(-x_i)) - N = P - H_l - d,$$

with the thermal particles above the filled levels $P = \sum_{i \notin \mathcal{S}} g_i f(x_i)$ and the thermal holes below them $H_l = \sum_{i \in \mathcal{S}} g_i f(-x_i)$. Rule: split the sum into the levels outside and inside $\mathcal{S}$; inside use $f(x) = 1 - f(-x)$; then $\sum_{\mathcal{S}} g_i - N = -d$. The condition $\sum gf = N$ becomes $P = H_l + d$, and for a closed shell simply $\ln P = \ln H_l$: the thermal particles balance the thermal holes. No numbers close to 1 are added and no large number is subtracted; each hole factor is computed as $f(-x)$ directly, never as $1 - f$. The solver solves $\ln(P + d_-) - \ln(H_l + d_+) = 0$ with $d_\pm = \max(\pm d, 0)$, adding each sum in the form $\ln \sum e^{t_i} = t_{max} + \ln \sum e^{t_i - t_{max}}$ (the **log-sum-exp**, which never overflows or underflows), by Newton's method in a bracket and then bisection down to neighbouring double-precision numbers (`Revision/kohn_sham/solver/src/mermin.rs`). The record checks every one of the 135 roots against a root computed with 40 significant digits by mpmath: all lie within their rounding bound, the largest difference is $2.4 \times 10^{-16}\, m$ (`Revision/kohn_sham/reports/ks-rust-mermin-roots.json`, check solver_mu_within_rounding_bound).

The sea holes: where the filling convention stops being reasonable. The CONVENTION of Section 15.2 never occupies the negative branch, not even thermally. How good is that? Without interaction the sea's brane band (block type $j = -1$, even parity, label 0) has the levels $-\varepsilon_{band}(n_2)$ (Section 15.4). If the sea were treated thermally, each of its orbitals would be empty with the probability $1 - f((-\varepsilon_{band} - \mu)/T) = f((\varepsilon_{band} + \mu)/T) = 1/(1 + e^{(\mu + \varepsilon_{band})/T})$; such an empty sea orbital is a **thermal hole**, which a full quantum treatment would count as an antiparticle of the same universe. The record computes the number of these holes for every thermal state as a DIAGNOSTIC (check thermo_sea_hole_diagnostic_computed): it exceeds 1 per cent of N in 15 of the 135 states, all at $a_{4,0} \geq 1$, and reaches $30.98\, N$ in `N8_lamm1_a20_T50` ($N = 8$, $-\lambda_1$, $a_{4,0} = 2$, $T = 0.05$). There the band has been squeezed so close to $\varepsilon = 0$ that the temperature excites the sea as easily as the particles, μ itself is negative (-0.0977), and the particle-only ensemble is outside its range of validity; a thermal treatment of the sea is OPEN. These thermal holes are excitations inside one universe; they say nothing about pairs of universes or about the matter-antimatter asymmetry.

15.27 Example: thermodynamics (Notebook 15d)

Notebook 15d runs the solver's command `single` for 20 free thermal states ($N = 8$ and 136) and reads their final levels exactly. From these levels alone it recomputes, in plain Python, the chemical potential (with mpmath at 40 digits), E, S, F, Ω, C_V and $dN/d\mu$, and compares them with the record. It shows why the direct count is too coarse (Figure 15d.1), draws $\mu(T)$ with

the two-level formula (Figure 15d.2), F and S along the history (Figure 15d.3), the heat capacity (Figure 15d.4), the occupations (Figure 15d.5), the sea-hole diagnostic (Figure 15d.6) and the effect of the interaction on F (Figure 15d.7). It needs Rust, takes about half a minute, and ends with ALL 15 CHECKS PASSED (notebook 15d).

What to look for: in Figure 15d.1 the orange staircase of the double-precision count against the smooth blue line of the exact count; in Figure 15d.2 the straight start of $\mu(T)$ from the middle of the gap; in Figure 15d.4 how the heat capacity of $N = 8$ wakes up at ever lower temperatures as the history closes the gap; in Figure 15d.6 the values above the 1 per cent line late in the history.

15.28 How to run Notebook 15d

Step 1. What this notebook does and what it needs.

Notebook 15d (Thermodynamics of the Kohn-Sham gas along the deflating history) is the file `Revision/textbook/notebooks/15d_thermodynamics.ipynb` of the repository Dirac_claude. It builds the Rust Kohn-Sham solver with cargo (a full build of about a minute when the program is missing, a second when it is up to date), runs it for the free thermal states N = 8 and N = 136 of dirac16complex at the slices of the deflating history, recomputes from the solver's levels the chemical potential (at 40 digits and with the well-conditioned double-precision balance), the energy, entropy, free energy, grand potential, heat capacity and the sea-hole diagnostic of the committed Revision record, and draws the chemical potential, free energy, entropy and heat capacity as functions of the temperature. The solver writes its output files (about 0.6 MB) into the folder `Revision/kohn_sham/solver/target/textbook_15d`, which git ignores. It needs a computer with Windows 11, macOS or Linux, an internet connection for the installation, the program Git, and Python 3.12 or newer (the notebooks were built with Python 3.14.5) with these packages at exactly these versions: numpy 2.4.6, sympy 1.14.0, mpmath 1.3.0, matplotlib 3.11.0, jupyterlab 4.4.10, nbformat 5.10.4, nbclient 0.10.2, ipykernel 7.1.0 and nbconvert 7.16.6. The notebook itself imports numpy, mpmath and matplotlib; the other packages run Jupyter, the program that shows and runs notebooks. It also needs Rust (the program cargo, version 1.91.1 or newer), because it runs the Rust program revision_ks_solver, which is part of the repository and is built on your computer.

Step 2. Install Git and Python (once per computer).

A terminal is the window in which you type commands: on Windows the app Windows PowerShell (or Terminal), on macOS the app Terminal (it runs the shell zsh), on Linux any terminal (it runs the shell bash). Type every command of this section into a terminal exactly as printed, one line at a time, and press Enter after each line.

Windows: download Git from https://git-scm.com/download/win and install it with the default choices. Download Python from https://www.python.org/downloads/ and run the installer; in its first window tick the box "Add python.exe to PATH" before you click "Install Now".

macOS: download Python from https://www.python.org/downloads/ and run the installer. Then open the app Terminal and run this command, which installs Git and the compiler tools:

macOS (zsh):

```
xcode-select --install
```

Linux (Debian or Ubuntu; other distributions have packages of the same names): run these two commands:

Linux (bash):

```
sudo apt update
sudo apt install git python3 python3-venv
```

Then close the terminal and open a NEW one (a terminal opened before the installation does not know the new programs), and check the version of Python; it must print 3.12 or a higher number:

Windows (PowerShell):

```
py -3 --version
```

macOS (zsh) and Linux (bash):

```
python3 --version
```

If an older Linux prints a lower number (Ubuntu 22.04 has Python 3.10), install Python 3.12 with the following three commands, and in Step 3 type `python3.12` instead of `python3` in the command that creates the environment:

Linux (bash), only when the version is too low:

```
sudo add-apt-repository ppa:deadsnakes/ppa
sudo apt update
sudo apt install python3.12 python3.12-venv
```

Step 3. Get the repository and install the packages (once per computer).

The commands below download the repository (a few hundred megabytes; the folder then needs up to about 1 GB of disk space) into the folder Dirac_claude inside your home folder, create a private Python environment in the folder dirac-book-env inside your home folder (a private environment is a folder with its own copy of Python and of the packages, so that nothing else on your computer is changed), activate it (from then on the commands `python` and `jupyter` typed in this terminal are those of the environment, and the prompt starts with (dirac-book-env)), and install the packages at the pinned versions (this downloads about 90 MB and takes a few minutes; the environment takes about 400 MB of disk space). If you have done this step before, for this or for another notebook, skip it and go to Step 4; to get the newest version of the repository, run `git pull` in the repository folder after Step 4.

Windows (PowerShell):

```
cd $HOME
git clone https://github.com/once-ere/Dirac_claude.git
py -3 -m venv "$HOME\dirac-book-env"
Set-ExecutionPolicy -ExecutionPolicy RemoteSigned -Scope Process -Force
```

```
& "$HOME\dirac-book-env\Scripts\Activate.ps1"
python -m pip install --upgrade pip
python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
```

The line with `Set-ExecutionPolicy` allows PowerShell to run the activation script in this one window only; it changes nothing permanently.

macOS (zsh):

```
cd ~
git clone https://github.com/once-ere/Dirac_claude.git
python3 -m venv ~/dirac-book-env
source ~/dirac-book-env/bin/activate
python -m pip install --upgrade pip
python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
```

Linux (bash):

```
cd ~
git clone https://github.com/once-ere/Dirac_claude.git
python3 -m venv ~/dirac-book-env
source ~/dirac-book-env/bin/activate
python -m pip install --upgrade pip
python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
```

Step 4. In every new terminal: activate the environment and go into the repository folder.

Every later step starts in the repository folder with the environment active. Run these lines whenever you open a new terminal (they do no harm if the environment is already active):

Windows (PowerShell):

```
Set-ExecutionPolicy -ExecutionPolicy RemoteSigned -Scope Process -Force
& "$HOME\dirac-book-env\Scripts\Activate.ps1"
cd "$HOME\Dirac_claude"
```

macOS (zsh) and Linux (bash):

```
source ~/dirac-book-env/bin/activate
cd ~/Dirac_claude
```

Step 5. Install Rust and build the Rust program (Rust once per computer, the build once per program).

Windows: download `rustup-init.exe` from https://rustup.rs, run it and accept the default choices; if it reports that the Visual Studio C++ Build Tools are missing, let it install them (or install the workload "Desktop development with C++" from https://visualstudio.microsoft.com/visual-cpp-build-tools/ and run `rustup-init.exe` again). macOS and Linux: run the command below and accept the default choice (on Linux first run `sudo apt install build-essential`, which provides the linker that Rust needs).

macOS (zsh) and Linux (bash):

```
curl --proto "=https" --tlsv1.2 -sSf https://sh.rustup.rs | sh
```

Then close the terminal, open a new one, do Step 4 again, and check the version of cargo; it must print 1.91.1 or a newer version:

Windows, macOS and Linux:

```
cargo --version
```

Build the program with the following command, in the repository folder (the same command on all three systems):

Windows, macOS and Linux:

```
cargo build --release --manifest-path Revision/kohn_sham/solver/Cargo.toml
```

The first build takes about 1 minute; later builds reuse the result and take a few seconds. The program is then the file `Revision/kohn_sham/solver/target/release/revision_ks_solver` (on Windows with the ending `.exe`). The notebook runs the same build command itself before it uses the program (it takes a second when the program is up to date), so the notebook also works if you skip this build; building here first shows any problem with Rust before the notebook starts.

Step 6. Run the notebook in JupyterLab.

In the repository folder, with the environment active, run these two lines (the first one goes into the folder of the notebooks):

Windows, macOS and Linux:

```
cd Revision/textbook/notebooks
jupyter lab 15d_thermodynamics.ipynb
```

JupyterLab opens in your web browser and shows the notebook (if no browser window opens, copy the address that starts with `http://localhost:8888/lab` from the terminal into the address bar of your browser). The name at the top right of the notebook must read Python 3 (ipykernel). Choose the menu Run > Run All Cells. While a cell runs, the label to its left shows `[*]`; when it has finished, the label shows a number. The notebook has finished when the last code cell shows a number; this takes about 30 seconds on a typical laptop. Scroll to the end and compare the last printed lines with the lines in the step "What the notebook writes and what you must see" below.

To keep the results, save the notebook (menu File > Save Notebook). To stop JupyterLab, choose the menu File > Shut Down, or press Ctrl+C twice in the terminal.

Step 7. Or run the notebook without a browser (headless).

In the repository folder, with the environment active, run:

Windows, macOS and Linux:

```
cd Revision/textbook/notebooks
jupyter nbconvert --to notebook --execute --inplace 15d_thermodynamics.ipynb
```

This runs every cell from the top to the bottom and saves the results into the notebook file. A failed check stops it with an error message that contains AssertionError and the name of the check. If the command ends with a line that starts with `[NbConvertApp] Writing` and shows no error, every check passed; open the notebook with `jupyter lab 15d_thermodynamics.ipynb` (in the same folder, without running the cells again) to read the printed lines and see the figures.

Step 8. What the notebook writes and what you must see.

The notebook writes (or overwrites) these files:

- `Revision/textbook/figures/15d.captions.json`
- `Revision/textbook/figures/15d_1_root_conditioning.png`
- `Revision/textbook/figures/15d_2_chemical_potential.png`
- `Revision/textbook/figures/15d_3_free_energy_entropy.png`
- `Revision/textbook/figures/15d_4_heat_capacity.png`
- `Revision/textbook/figures/15d_5_occupations.png`
- `Revision/textbook/figures/15d_6_sea_holes.png`
- `Revision/textbook/figures/15d_7_interaction_free_energy.png`

It changes no other file of the repository except the Rust build folder `target` next to each `Cargo.toml` it builds (inside it the notebook keeps the raw output of its program runs in `Revision/kohn_sham/solver/target/textbook_15d`, which git ignores); running it headless or saving it in JupyterLab also rewrites the notebook file itself. It does not use the internet while it runs. The files it writes are the same files that are stored in the repository (on another computer a figure may differ in a few bytes, which is harmless). To get the stored versions back, run this command in the repository folder (it also undoes every change you made yourself in the folder Revision/textbook):

Windows, macOS and Linux:

```
git checkout -- Revision/textbook
```

Every check of the notebook prints a line that starts with PASS. At the end of the notebook (the output of its last code cell) you must see exactly these lines:

```
PASS every figure file of this notebook exists
ALL 15 CHECKS PASSED (notebook 15d)
```

and the notebook must show 7 figures below the cells that draw them.

Step 9. If something goes wrong.

- "ModuleNotFoundError: No module named ..." in the notebook: JupyterLab was started without the environment. Stop it (menu File > Shut Down), do Step 4, and start it again. If the error remains, another Python installation has registered its own kernel called python3; with the environment active, run the following command and start JupyterLab again:

```
python -m ipykernel install --user --name python3
```

- "FileNotFoundError: The repository folder was not found": the notebook was opened from a copy outside the repository. Open the file `Revision/textbook/notebooks/15d_thermodynamics.ipynb` inside the folder Dirac_claude.
- "fatal: destination path 'Dirac_claude' already exists" in Step 3: the repository was downloaded before; skip the line with `git clone`.
- Windows: "running scripts is disabled on this system": run the line with `Set-ExecutionPolicy` and then the activation line again. "py is not recognized": use `python` instead of `py -3`; "python is not recognized": install Python again and tick "Add python.exe to PATH".
- Linux: "ensurepip is not available" when the environment is created: run `sudo apt install python3-venv` and repeat Step 3.
- "jupyter is not recognized" or "command not found: jupyter": the environment is not active; do Step 4. If the environment is active and the message stays, the programs jupyter-lab and jupyter-nbconvert are not in the folders where the terminal looks for programs (`python -m jupyter` does not help then: it has to find the same programs). Start them through Python itself, in the folder of the notebook: the first command below does what `jupyter lab` does, the second what the headless command does:

```
python -m jupyterlab 15d_thermodynamics.ipynb
python -m nbconvert --execute --inplace 15d_thermodynamics.ipynb
```

- Windows: the headless run prints a RuntimeWarning that mentions the "Proactor event loop" and zmq: this is a message of the package pyzmq, not an error; the run continues normally.
- A red box with "Matplotlib is building the font cache; this may take a moment." in the first run after the installation: this is a message, not an error; the run continues and the message does not come again.
- An AssertionError names a check that failed: choose the menu Kernel > Restart Kernel and Run All Cells; if it fails again, install the packages again with the pip commands of Step 3, because a different package version can change the last digits of a result.

- "cargo is not recognized" or "command not found: cargo" or "cargo was not found": open a new terminal after installing Rust, do Step 4 again, and start JupyterLab from this terminal.
- "linker link.exe not found" (Windows) or "linker cc not found" (Linux): install the C++ Build Tools (Windows) or build-essential (Linux) as described in Step 5 and build again.
- You want the disk space of the solver output back: the folder `Revision/kohn_sham/solver/target/textbook_15d` holds only the raw output of the last run (40 files, about 0.6 MB), which git ignores; delete it at any time, the notebook writes it again.

15.29 Notebook 15d: complete text

This section prints the complete text of the notebook file `Revision/textbook/notebooks/15d_thermodynamics.ipynb`: every cell in order, with the output that the stored, executed notebook holds. A text cell (Jupyter calls it a markdown cell) is printed in a frame after the label Text cell. A code cell is printed after the label In [k], where k is the number that Jupyter gives the cell when it runs it; the text that the cell prints follows after the label Out [k], and every figure that the cell draws follows as a figure with its caption.

Text cell:

```
## 1. What this notebook computes

At a temperature $T > 0$ the particles of the Kohn-Sham gas no longer fill exactly
the lowest levels: each level is occupied with the **Fermi-Dirac** probability
$f = 1/(1 + e^{(\varepsilon - \mu)/T})$, where the **chemical potential** $\mu$ is
fixed by the particle number. This is Mermin's finite-temperature version of
Kohn-Sham theory. The Revision record holds 135 such states (three particle numbers,
three couplings, five slices of the history, three temperatures). This notebook

- runs the Rust solver for the free states ($\lambda = 0$) of $N = 8$ and $N = 136$
  and reads its levels;
- recomputes from these levels, in plain Python, $\mu$ (at 40 digits with mpmath),
  the energy $E$, the entropy $S$, the free energy $F = E - TS$, the grand
  potential $\Omega$, the heat capacity $C_V$ and $dN/d\mu$, and compares all of
  them with the record;
- explains why the solver computes $\mu$ from a **balance of particles and holes**
  instead of the direct count, and shows the difference;
- draws $\mu$, $F$, $S$ and $C_V$ as continuous functions of $T$, the occupations at
  three temperatures, the sea-hole diagnostic of the filling convention, and the
  effect of the interaction on $F$.

It draws seven figures and takes about half a minute.
```

Text cell:

```
## 2. How to run this notebook

**Step 1. What this notebook does and what it needs.**
```

Notebook 15d (Thermodynamics of the Kohn-Sham gas along the deflating history) is the file ‘Revision/textbook/notebooks/15d_thermodynamics.ipynb‘ of the repository Dirac_claude. It builds the Rust Kohn-Sham solver with cargo (a full build of about a minute when the program is missing, a second when it is up to date), runs it for the free thermal states N = 8 and N = 136 of dirac16complex at the slices of the deflating history, recomputes from the solver’s levels the chemical potential (at 40 digits and with the well-conditioned double-precision balance), the energy, entropy, free energy, grand potential, heat capacity and the sea-hole diagnostic of the committed Revision record, and draws the chemical potential, free energy, entropy and heat capacity as functions of the temperature. The solver writes its output files (about 0.6 MB) into the folder ‘Revision/kohn_sham/solver/target/textbook_15d‘, which git ignores. It needs a computer with Windows 11, macOS or Linux, an internet connection for the installation, the program Git, and Python 3.12 or newer (the notebooks were built with Python 3.14.5) with these packages at exactly these versions: numpy 2.4.6, sympy 1.14.0, mpmath 1.3.0, matplotlib 3.11.0, jupyterlab 4.4.10, nbformat 5.10.4, nbclient 0.10.2, ipykernel 7.1.0 and nbconvert 7.16.6. The notebook itself imports numpy, mpmath and matplotlib; the other packages run Jupyter, the program that shows and runs notebooks. It also needs Rust (the program cargo, version 1.91.1 or newer), because it runs the Rust program revision_ks_solver, which is part of the repository and is built on your computer.

Step 2. Install Git and Python (once per computer).

A terminal is the window in which you type commands: on Windows the app Windows PowerShell (or Terminal), on macOS the app Terminal (it runs the shell zsh), on Linux any terminal (it runs the shell bash). Type every command of this section into a terminal exactly as printed, one line at a time, and press Enter after each line.

Windows: download Git from https://git-scm.com/download/win and install it with the default choices. Download Python from https://www.python.org/downloads/ and run the installer; in its first window tick the box "Add python.exe to PATH" before you click "Install Now".

macOS: download Python from https://www.python.org/downloads/ and run the installer. Then open the app Terminal and run this command, which installs Git and the compiler tools:

macOS (zsh):

```
xcode-select --install
```

Linux (Debian or Ubuntu; other distributions have packages of the same names): run these two commands:

Linux (bash):

```
sudo apt update
sudo apt install git python3 python3-venv
```

Then close the terminal and open a NEW one (a terminal opened before the installation does not know the new programs), and check the version of Python; it must print 3.12 or a higher number:

Windows (PowerShell):

```
py -3 --version
```

macOS (zsh) and Linux (bash):

```
python3 --version
```

If an older Linux prints a lower number (Ubuntu 22.04 has Python 3.10), install Python 3.12 with the following three commands, and in Step 3 type ‘python3.12‘ instead of ‘python3‘ in the command that creates the environment:

Linux (bash), only when the version is too low:

```
sudo add-apt-repository ppa:deadsnakes/ppa
sudo apt update
sudo apt install python3.12 python3.12-venv
```

Step 3. Get the repository and install the packages (once per computer).

The commands below download the repository (a few hundred megabytes; the folder then needs up to about 1 GB of disk space) into the folder Dirac_claude inside your home folder, create a private Python environment in the folder dirac-book-env inside your home folder (a private environment is a folder with its own copy of Python and of the packages, so that nothing else on your computer is changed), activate it (from then on the commands ‘python‘ and ‘jupyter‘ typed in this terminal are those of the environment, and the prompt starts with (dirac-book-env)), and install the packages at the pinned versions (this downloads about 90 MB and takes a few minutes; the environment takes about 400 MB of disk space). If you have done this step before, for this or for another notebook, skip it and go to Step 4; to get the newest version of the repository, run ‘git pull‘ in the repository folder after Step 4.

Windows (PowerShell):

```
cd $HOME
git clone https://github.com/once-ere/Dirac_claude.git
py -3 -m venv "$HOME\dirac-book-env"
Set-ExecutionPolicy -ExecutionPolicy RemoteSigned -Scope Process -Force
& "$HOME\dirac-book-env\Scripts\Activate.ps1"
python -m pip install --upgrade pip
python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
```

The line with ‘Set-ExecutionPolicy‘ allows PowerShell to run the activation script in this one window only; it changes nothing permanently.

macOS (zsh):

```
cd ~
git clone https://github.com/once-ere/Dirac_claude.git
python3 -m venv ~/dirac-book-env
source ~/dirac-book-env/bin/activate
python -m pip install --upgrade pip
python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
```

Linux (bash):

```
cd ~
git clone https://github.com/once-ere/Dirac_claude.git
python3 -m venv ~/dirac-book-env
source ~/dirac-book-env/bin/activate
python -m pip install --upgrade pip
python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
```

Step 4. In every new terminal: activate the environment and go into the repository folder.

Every later step starts in the repository folder with the environment active. Run these lines whenever you open a new terminal (they do no harm if the environment is already active):

Windows (PowerShell):

```
Set-ExecutionPolicy -ExecutionPolicy RemoteSigned -Scope Process -Force
& "$HOME\dirac-book-env\Scripts\Activate.ps1"
cd "$HOME\Dirac_claude"
```

macOS (zsh) and Linux (bash):

```
source ~/dirac-book-env/bin/activate
cd ~/Dirac_claude
```

Step 5. Install Rust and build the Rust program (Rust once per computer, the build once per program).

Windows: download ‘rustup-init.exe‘ from https://rustup.rs, run it and accept the default choices; if it reports that the Visual Studio C++ Build Tools are missing, let it install them (or install the workload "Desktop development with C++" from https://visualstudio.microsoft.com/visual-cpp-build-tools/ and run ‘rustup-init.exe‘ again). macOS and Linux: run the command below and accept the default choice (on Linux first run ‘sudo apt install build-essential‘, which provides the linker that Rust needs).

macOS (zsh) and Linux (bash):

```
curl --proto "=https" --tlsv1.2 -sSf https://sh.rustup.rs | sh
```

Then close the terminal, open a new one, do Step 4 again, and check the version of cargo; it must print 1.91.1 or a newer version:

Windows, macOS and Linux:

```
cargo --version
```

Build the program with the following command, in the repository folder (the same command on all three systems):

Windows, macOS and Linux:

```
    cargo build --release --manifest-path Revision/kohn_sham/solver/Cargo.toml
```

The first build takes about 1 minute; later builds reuse the result and take a few seconds. The program is then the file ‘Revision/kohn_sham/solver/target/release/revision_ks_solver‘ (on Windows with the ending ‘.exe‘). The notebook runs the same build command itself before it uses the program (it takes a second when the program is up to date), so the notebook also works if you skip this build; building here first shows any problem with Rust before the notebook starts.

Step 6. Run the notebook in JupyterLab.

In the repository folder, with the environment active, run these two lines (the first one goes into the folder of the notebooks):

Windows, macOS and Linux:

```
    cd Revision/textbook/notebooks
    jupyter lab 15d_thermodynamics.ipynb
```

JupyterLab opens in your web browser and shows the notebook (if no browser window opens, copy the address that starts with ‘http://localhost:8888/lab‘ from the terminal into the address bar of your browser). The name at the top right of the notebook must read Python 3 (ipykernel). Choose the menu Run > Run All Cells. While a cell runs, the label to its left shows ‘[*]‘; when it has finished, the label shows a number. The notebook has finished when the last code cell shows a number; this takes about 30 seconds on a typical laptop. Scroll to the end and compare the last printed lines with the lines in the step "What the notebook writes and what you must see" below. To keep the results, save the notebook (menu File > Save Notebook). To stop JupyterLab, choose the menu File > Shut Down, or press Ctrl+C twice in the terminal.

Step 7. Or run the notebook without a browser (headless).

In the repository folder, with the environment active, run:

Windows, macOS and Linux:

```
    cd Revision/textbook/notebooks
    jupyter nbconvert --to notebook --execute --inplace 15d_thermodynamics.ipynb
```

This runs every cell from the top to the bottom and saves the results into the notebook file. A failed check stops it with an error message that contains AssertionError and the name of the check. If the command ends with a line that starts with ‘[NbConvertApp] Writing‘ and shows no error, every check passed; open the notebook with ‘jupyter lab 15d_thermodynamics.ipynb‘ (in the same folder, without running the cells again) to read the printed lines and see the figures.

Step 8. What the notebook writes and what you must see.

The notebook writes (or overwrites) these files:

- ‘Revision/textbook/figures/15d.captions.json‘
- ‘Revision/textbook/figures/15d_1_root_conditioning.png‘

- ‘Revision/textbook/figures/15d_2_chemical_potential.png‘
- ‘Revision/textbook/figures/15d_3_free_energy_entropy.png‘
- ‘Revision/textbook/figures/15d_4_heat_capacity.png‘
- ‘Revision/textbook/figures/15d_5_occupations.png‘
- ‘Revision/textbook/figures/15d_6_sea_holes.png‘
- ‘Revision/textbook/figures/15d_7_interaction_free_energy.png‘

It changes no other file of the repository except the Rust build folder ‘target‘ next to each ‘Cargo.toml‘ it builds (inside it the notebook keeps the raw output of its program runs in ‘Revision/kohn_sham/solver/target/textbook_15d‘, which git ignores); running it headless or saving it in JupyterLab also rewrites the notebook file itself. It does not use the internet while it runs. The files it writes are the same files that are stored in the repository (on another computer a figure may differ in a few bytes, which is harmless). To get the stored versions back, run this command in the repository folder (it also undoes every change you made yourself in the folder Revision/textbook):

Windows, macOS and Linux:

```
git checkout -- Revision/textbook
```

Every check of the notebook prints a line that starts with PASS. At the end of the notebook (the output of its last code cell) you must see exactly these lines:

```
PASS every figure file of this notebook exists
ALL 15 CHECKS PASSED (notebook 15d)
```

and the notebook must show 7 figures below the cells that draw them.

Step 9. If something goes wrong.

- "ModuleNotFoundError: No module named ..." in the notebook: JupyterLab was started without the environment. Stop it (menu File > Shut Down), do Step 4, and start it again. If the error remains, another Python installation has registered its own kernel called python3; with the environment active, run the following command and start JupyterLab again:

  ```
  python -m ipykernel install --user --name python3
  ```

- "FileNotFoundError: The repository folder was not found": the notebook was opened from a copy outside the repository. Open the file ‘Revision/textbook/notebooks/15d_thermodynamics.ipynb‘ inside the folder Dirac_claude.
- "fatal: destination path ’Dirac_claude’ already exists" in Step 3: the repository was downloaded before; skip the line with ‘git clone‘.
- Windows: "running scripts is disabled on this system": run the line with ‘Set-ExecutionPolicy‘ and then the activation line again. "py is not recognized": use ‘python‘ instead of ‘py -3‘; "python is not recognized": install Python again and tick "Add python.exe to PATH".
- Linux: "ensurepip is not available" when the environment is created: run ‘sudo apt install python3-venv‘ and repeat Step 3.
- "jupyter is not recognized" or "command not found: jupyter": the environment is not active; do Step 4. If the environment is active and the message stays, the programs jupyter-lab and jupyter-nbconvert are not in the folders where the terminal looks for programs (‘python -m jupyter‘ does not help then: it has to find the same programs). Start them through Python itself, in the folder of the notebook: the first command

below does what ‘jupyter lab‘ does, the second what the headless command does:

```
    python -m jupyterlab 15d_thermodynamics.ipynb
    python -m nbconvert --execute --inplace 15d_thermodynamics.ipynb
```

- Windows: the headless run prints a RuntimeWarning that mentions the "Proactor event loop" and zmq: this is a message of the package pyzmq, not an error; the run continues normally.
- A red box with "Matplotlib is building the font cache; this may take a moment." in the first run after the installation: this is a message, not an error; the run continues and the message does not come again.
- An AssertionError names a check that failed: choose the menu Kernel > Restart Kernel and Run All Cells; if it fails again, install the packages again with the pip commands of Step 3, because a different package version can change the last digits of a result.
- "cargo is not recognized" or "command not found: cargo" or "cargo was not found": open a new terminal after installing Rust, do Step 4 again, and start JupyterLab from this terminal.
- "linker link.exe not found" (Windows) or "linker cc not found" (Linux): install the C++ Build Tools (Windows) or build-essential (Linux) as described in Step 5 and build again.
- You want the disk space of the solver output back: the folder ‘Revision/kohn_sham/solver/target/textbook_15d‘ holds only the raw output of the last run (40 files, about 0.6 MB), which git ignores; delete it at any time, the notebook writes it again.

The first code cell below (the set-up cell) repeats these instructions as comments; then it imports the packages, finds the repository folder and defines the helpers ‘save_figure‘ (saves a figure and shows it), ‘check‘ (stops with an AssertionError when a check fails, prints a PASS line when it passes), ‘report‘ (prints a key number as a RESULT line) and ‘all_checks_passed‘ (prints the last line).

In [1]:

```
# HOW TO RUN NOTEBOOK 15d (the complete instructions)
#
# STEP 1. WHAT THIS NOTEBOOK DOES AND WHAT IT NEEDS.
#
# Notebook 15d (Thermodynamics of the Kohn-Sham gas along the deflating history) is the
# file Revision/textbook/notebooks/15d_thermodynamics.ipynb of the repository
# Dirac_claude. It builds the Rust Kohn-Sham solver with cargo (a full build of about a
# minute when the program is missing, a second when it is up to date), runs it for the
# free thermal states N = 8 and N = 136 of dirac16complex at the slices of the deflating
# history, recomputes from the solver's levels the chemical potential (at 40 digits and
# with the well-conditioned double-precision balance), the energy, entropy, free energy,
# grand potential, heat capacity and the sea-hole diagnostic of the committed Revision
# record, and draws the chemical potential, free energy, entropy and heat capacity as
# functions of the temperature. The solver writes its output files (about 0.6 MB) into
# the folder Revision/kohn_sham/solver/target/textbook_15d, which git ignores. It needs a
# computer with Windows 11, macOS or Linux, an internet connection for the installation,
# the program Git, and Python 3.12 or newer (the notebooks were built with Python 3.14.5)
# with these packages at exactly these versions: numpy 2.4.6, sympy 1.14.0, mpmath 1.3.0,
# matplotlib 3.11.0, jupyterlab 4.4.10, nbformat 5.10.4, nbclient 0.10.2, ipykernel 7.1.0
# and nbconvert 7.16.6. The notebook itself imports numpy, mpmath and matplotlib; the
```

```
# other packages run Jupyter, the program that shows and runs notebooks. It also needs
# Rust (the program cargo, version 1.91.1 or newer), because it runs the Rust program
# revision_ks_solver, which is part of the repository and is built on your computer.
#
# STEP 2. INSTALL GIT AND PYTHON (ONCE PER COMPUTER).
#
# A terminal is the window in which you type commands: on Windows the app Windows
# PowerShell (or Terminal), on macOS the app Terminal (it runs the shell zsh), on Linux
# any terminal (it runs the shell bash). Type every command of this section into a
# terminal exactly as printed, one line at a time, and press Enter after each line.
#
# Windows: download Git from https://git-scm.com/download/win and install it with the
# default choices. Download Python from https://www.python.org/downloads/ and run the
# installer; in its first window tick the box "Add python.exe to PATH" before you click
# "Install Now".
#
# macOS: download Python from https://www.python.org/downloads/ and run the installer.
# Then open the app Terminal and run this command, which installs Git and the compiler
# tools:
#
# macOS (zsh):
#     xcode-select --install
#
# Linux (Debian or Ubuntu; other distributions have packages of the same names): run
# these two commands:
#
# Linux (bash):
#     sudo apt update
#     sudo apt install git python3 python3-venv
#
# Then close the terminal and open a NEW one (a terminal opened before the installation
# does not know the new programs), and check the version of Python; it must print 3.12 or
# a higher number:
#
# Windows (PowerShell):
#     py -3 --version
#
# macOS (zsh) and Linux (bash):
#     python3 --version
#
# If an older Linux prints a lower number (Ubuntu 22.04 has Python 3.10), install Python
# 3.12 with the following three commands, and in Step 3 type python3.12 instead of
# python3 in the command that creates the environment:
#
# Linux (bash), only when the version is too low:
#     sudo add-apt-repository ppa:deadsnakes/ppa
#     sudo apt update
#     sudo apt install python3.12 python3.12-venv
#
# STEP 3. GET THE REPOSITORY AND INSTALL THE PACKAGES (ONCE PER COMPUTER).
#
# The commands below download the repository (a few hundred megabytes; the folder then
# needs up to about 1 GB of disk space) into the folder Dirac_claude inside your home
# folder, create a private Python environment in the folder dirac-book-env inside your
```

```
# home folder (a private environment is a folder with its own copy of Python and of the
# packages, so that nothing else on your computer is changed), activate it (from then on
# the commands python and jupyter typed in this terminal are those of the environment,
# and the prompt starts with (dirac-book-env)), and install the packages at the pinned
# versions (this downloads about 90 MB and takes a few minutes; the environment takes
# about 400 MB of disk space). If you have done this step before, for this or for another
# notebook, skip it and go to Step 4; to get the newest version of the repository, run
# git pull in the repository folder after Step 4.
#
# Windows (PowerShell):
#     cd $HOME
#     git clone https://github.com/once-ere/Dirac_claude.git
#     py -3 -m venv "$HOME\dirac-book-env"
#     Set-ExecutionPolicy -ExecutionPolicy RemoteSigned -Scope Process -Force
#     & "$HOME\dirac-book-env\Scripts\Activate.ps1"
#     python -m pip install --upgrade pip
#     python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
#     python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
#     python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
#
# The line with Set-ExecutionPolicy allows PowerShell to run the activation script in
# this one window only; it changes nothing permanently.
#
# macOS (zsh):
#     cd ~
#     git clone https://github.com/once-ere/Dirac_claude.git
#     python3 -m venv ~/dirac-book-env
#     source ~/dirac-book-env/bin/activate
#     python -m pip install --upgrade pip
#     python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
#     python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
#     python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
#
# Linux (bash):
#     cd ~
#     git clone https://github.com/once-ere/Dirac_claude.git
#     python3 -m venv ~/dirac-book-env
#     source ~/dirac-book-env/bin/activate
#     python -m pip install --upgrade pip
#     python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
#     python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
#     python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
#
# STEP 4. IN EVERY NEW TERMINAL: ACTIVATE THE ENVIRONMENT AND GO INTO THE REPOSITORY
# FOLDER.
#
# Every later step starts in the repository folder with the environment active. Run these
# lines whenever you open a new terminal (they do no harm if the environment is already
# active):
#
# Windows (PowerShell):
#     Set-ExecutionPolicy -ExecutionPolicy RemoteSigned -Scope Process -Force
#     & "$HOME\dirac-book-env\Scripts\Activate.ps1"
#     cd "$HOME\Dirac_claude"
```

```
#
# macOS (zsh) and Linux (bash):
#     source ~/dirac-book-env/bin/activate
#     cd ~/Dirac_claude
#
# STEP 5. INSTALL RUST AND BUILD THE RUST PROGRAM (RUST ONCE PER COMPUTER, THE BUILD ONCE
# PER PROGRAM).
#
# Windows: download rustup-init.exe from https://rustup.rs, run it and accept the default
# choices; if it reports that the Visual Studio C++ Build Tools are missing, let it
# install them (or install the workload "Desktop development with C++" from
# https://visualstudio.microsoft.com/visual-cpp-build-tools/ and run rustup-init.exe
# again). macOS and Linux: run the command below and accept the default choice (on Linux
# first run sudo apt install build-essential, which provides the linker that Rust needs).
#
# macOS (zsh) and Linux (bash):
#     curl --proto "=https" --tlsv1.2 -sSf https://sh.rustup.rs | sh
#
# Then close the terminal, open a new one, do Step 4 again, and check the version of
# cargo; it must print 1.91.1 or a newer version:
#
# Windows, macOS and Linux:
#     cargo --version
#
# Build the program with the following command, in the repository folder (the same
# command on all three systems):
#
# Windows, macOS and Linux:
#     cargo build --release --manifest-path Revision/kohn_sham/solver/Cargo.toml
#
# The first build takes about 1 minute; later builds reuse the result and take a few
# seconds. The program is then the file
# Revision/kohn_sham/solver/target/release/revision_ks_solver (on Windows with the ending
# .exe). The notebook runs the same build command itself before it uses the program (it
# takes a second when the program is up to date), so the notebook also works if you skip
# this build; building here first shows any problem with Rust before the notebook starts.
#
# STEP 6. RUN THE NOTEBOOK IN JUPYTERLAB.
#
# In the repository folder, with the environment active, run these two lines (the first
# one goes into the folder of the notebooks):
#
# Windows, macOS and Linux:
#     cd Revision/textbook/notebooks
#     jupyter lab 15d_thermodynamics.ipynb
#
# JupyterLab opens in your web browser and shows the notebook (if no browser window
# opens, copy the address that starts with http://localhost:8888/lab from the terminal
# into the address bar of your browser). The name at the top right of the notebook must
# read Python 3 (ipykernel). Choose the menu Run > Run All Cells. While a cell runs, the
# label to its left shows [*]; when it has finished, the label shows a number. The
# notebook has finished when the last code cell shows a number; this takes about 30
# seconds on a typical laptop. Scroll to the end and compare the last printed lines with
# the lines in the step "What the notebook writes and what you must see" below. To keep
```

```
# the results, save the notebook (menu File > Save Notebook). To stop JupyterLab, choose
# the menu File > Shut Down, or press Ctrl+C twice in the terminal.
#
# STEP 7. OR RUN THE NOTEBOOK WITHOUT A BROWSER (HEADLESS).
#
# In the repository folder, with the environment active, run:
#
# Windows, macOS and Linux:
#     cd Revision/textbook/notebooks
#     jupyter nbconvert --to notebook --execute --inplace 15d_thermodynamics.ipynb
#
# This runs every cell from the top to the bottom and saves the results into the notebook
# file. A failed check stops it with an error message that contains AssertionError and
# the name of the check. If the command ends with a line that starts with [NbConvertApp]
# Writing and shows no error, every check passed; open the notebook with jupyter lab
# 15d_thermodynamics.ipynb (in the same folder, without running the cells again) to read
# the printed lines and see the figures.
#
# STEP 8. WHAT THE NOTEBOOK WRITES AND WHAT YOU MUST SEE.
#
# The notebook writes (or overwrites) these files:
#
# - Revision/textbook/figures/15d.captions.json
# - Revision/textbook/figures/15d_1_root_conditioning.png
# - Revision/textbook/figures/15d_2_chemical_potential.png
# - Revision/textbook/figures/15d_3_free_energy_entropy.png
# - Revision/textbook/figures/15d_4_heat_capacity.png
# - Revision/textbook/figures/15d_5_occupations.png
# - Revision/textbook/figures/15d_6_sea_holes.png
# - Revision/textbook/figures/15d_7_interaction_free_energy.png
#
# It changes no other file of the repository except the Rust build folder target next to
# each Cargo.toml it builds (inside it the notebook keeps the raw output of its program
# runs in Revision/kohn_sham/solver/target/textbook_15d, which git ignores); running it
# headless or saving it in JupyterLab also rewrites the notebook file itself. It does not
# use the internet while it runs. The files it writes are the same files that are stored
# in the repository (on another computer a figure may differ in a few bytes, which is
# harmless). To get the stored versions back, run this command in the repository folder
# (it also undoes every change you made yourself in the folder Revision/textbook):
#
# Windows, macOS and Linux:
#     git checkout -- Revision/textbook
#
# Every check of the notebook prints a line that starts with PASS. At the end of the
# notebook (the output of its last code cell) you must see exactly these lines:
#
#     PASS every figure file of this notebook exists
#     ALL 15 CHECKS PASSED (notebook 15d)
#
# and the notebook must show 7 figures below the cells that draw them.
#
# STEP 9. IF SOMETHING GOES WRONG.
#
# - "ModuleNotFoundError: No module named ..." in the notebook: JupyterLab was started
```

```
#   without the environment. Stop it (menu File > Shut Down), do Step 4, and start it
#   again. If the error remains, another Python installation has registered its own
#   kernel called python3; with the environment active, run the following command and
#   start JupyterLab again:
#     python -m ipykernel install --user --name python3
# - "FileNotFoundError: The repository folder was not found": the notebook was opened
#   from a copy outside the repository. Open the file
#   Revision/textbook/notebooks/15d_thermodynamics.ipynb inside the folder Dirac_claude.
# - "fatal: destination path 'Dirac_claude' already exists" in Step 3: the repository was
#   downloaded before; skip the line with git clone.
# - Windows: "running scripts is disabled on this system": run the line with
#   Set-ExecutionPolicy and then the activation line again. "py is not recognized": use
#   python instead of py -3; "python is not recognized": install Python again and tick
#   "Add python.exe to PATH".
# - Linux: "ensurepip is not available" when the environment is created: run sudo apt
#   install python3-venv and repeat Step 3.
# - "jupyter is not recognized" or "command not found: jupyter": the environment is not
#   active; do Step 4. If the environment is active and the message stays, the programs
#   jupyter-lab and jupyter-nbconvert are not in the folders where the terminal looks for
#   programs (python -m jupyter does not help then: it has to find the same programs).
#   Start them through Python itself, in the folder of the notebook: the first command
#   below does what jupyter lab does, the second what the headless command does:
#     python -m jupyterlab 15d_thermodynamics.ipynb
#     python -m nbconvert --execute --inplace 15d_thermodynamics.ipynb
# - Windows: the headless run prints a RuntimeWarning that mentions the "Proactor event
#   loop" and zmq: this is a message of the package pyzmq, not an error; the run
#   continues normally.
# - A red box with "Matplotlib is building the font cache; this may take a moment." in
#   the first run after the installation: this is a message, not an error; the run
#   continues and the message does not come again.
# - An AssertionError names a check that failed: choose the menu Kernel > Restart Kernel
#   and Run All Cells; if it fails again, install the packages again with the pip
#   commands of Step 3, because a different package version can change the last digits of
#   a result.
# - "cargo is not recognized" or "command not found: cargo" or "cargo was not found":
#   open a new terminal after installing Rust, do Step 4 again, and start JupyterLab from
#   this terminal.
# - "linker link.exe not found" (Windows) or "linker cc not found" (Linux): install the
#   C++ Build Tools (Windows) or build-essential (Linux) as described in Step 5 and build
#   again.
# - You want the disk space of the solver output back: the folder
#   Revision/kohn_sham/solver/target/textbook_15d holds only the raw output of the last
#   run (40 files, about 0.6 MB), which git ignores; delete it at any time, the notebook
#   writes it again.
#
# ------------------------------------------------------------------------------------

## 3. The words used in this notebook

- **Temperature** $T$: measured in units of the mass $m$ (Boltzmann's constant is
  1).
- **Fermi-Dirac occupation** $f(x) = 1/(1 + e^{x})$ with $x = (\varepsilon - \mu)/T$:
  the probability that a level of energy $\varepsilon$ is occupied. It is 1 far below
  $\mu$, 0 far above, and $1/2$ at $\varepsilon = \mu$. A useful identity:
  $1 - f(x) = f(-x)$.
- **Chemical potential** $\mu$: the number that makes the occupations add up to the
  particle number, $\sum g f = N$ ($g$ the degeneracy of a level).
- **Entropy** $S = -\sum g[f\ln f + (1 - f)\ln(1 - f)]$: a measure of how many
  microscopic arrangements the gas can take.
- **Free energy** $F = E - TS$ and **grand potential** $\Omega = F - \mu N$.
- **Heat capacity** $C_V = dE/dT = T\,dS/dT$ at fixed $N$: how much energy one
  unit of temperature costs.
- **Activated**: a gas whose lowest empty level lies a gap $\Delta$ above the
  highest occupied one; at $T \ll \Delta$ the thermal excitations are suppressed like
```

```
  $e^{-\Delta/(2T)}$.
- **Hole**: an empty place in a level that is normally occupied.
- **Sea**: the levels of the negative branch, which the filling CONVENTION of the
  record leaves out (normal ordering); **sea holes** would be thermal antiparticles.
- **Double precision**: the computer's usual numbers, with about 16 significant
  digits; **40 digits**: mpmath's numbers with as many digits as asked for.
- **Conditioning**: how strongly a result reacts to small errors of the input.
```

Text cell:

```
## 4. The physical and mathematical situation

The Kohn-Sham states of dirac16complex live in the author's metric, with 3-space
$x_1, x_2, x_3$ inflating like $e^{a_4}$, the three extra times $x_5, x_6, x_7$
deflating like $e^{-a_4}$, the time $x_4$ and the hidden direction $x_0$ (coordinate
$y$). The history $a_4 = AHx_4$ is a PRESCRIBED BACKGROUND, and each thermal state
is an instantaneous state at one slice $a_{4,0}$.

**Mermin's functional** (Revision record ks-theory.json, thermodynamics): with the
levels $\varepsilon_i$ (degeneracy $g_i$) of the Kohn-Sham Hamiltonian,

$$\sum_i g_i f_i = N, \quad E = \sum_i g_i f_i\varepsilon_i -
2\,\mathrm{Vol}_7\!\int e^{6Hy}e_{int}\,dy, \quad
S = -\sum_i g_i[f_i\ln f_i + (1 - f_i)\ln(1 - f_i)],$$
$$F = E - TS, \qquad \Omega = -T\sum_i g_i\ln(1 + e^{-(\varepsilon_i - \mu)/T})
- 2\,\mathrm{Vol}_7\!\int e^{6Hy}e_{int}\,dy = F - \mu N .$$

Without interaction ($\lambda = 0$) the levels do not depend on $T$ and $e_{int} = 0$,
so everything follows from the levels. Then the heat capacity has a closed form:
differentiating $\sum g f = N$ at fixed $N$ gives $d\mu/dT$, and inserting it into
$dE/dT$ gives, with $w_i = g_i f_i(1 - f_i)$ and $d_i = \varepsilon_i - \mu$,

$$C_V = \frac{1}{T^2}\left[\sum_i w_i d_i^2 - \frac{(\sum_i w_i d_i)^2}{\sum_i
w_i}\right], \qquad \frac{dN}{d\mu} = \frac{1}{T}\sum_i w_i .$$

(Line by line: $df/dx = -f(1-f)$; $dx_i/dT = -d_i/T^2 - (d\mu/dT)/T$; fixed $N$ means
$\sum w_i\,dx_i/dT = 0$, so $d\mu/dT = -\sum w_i d_i/(T\sum w_i)$; then
$dE/dT = -\sum w_i\varepsilon_i\,dx_i/dT$, and replacing $\varepsilon_i$ by $d_i$
changes nothing because $\sum w_i\,dx_i/dT = 0$.)

**The filling convention** (a CONVENTION whose justification is OPEN): particles fill
only the positive branch and the zero modes; the negative branch (the sea) is never
occupied thermally. The record measures how good this is: the **sea holes** that the
sea's brane band would carry at the same $\mu$ and $T$.

**Parameters**: $H = m = 1$, $L = 3$, $\Delta k = 0.25$, $T = 0.01, 0.02, 0.05$; $N$
counts the doubled system (universe and Z2 image, the brane being ASSUMED).
```

Text cell:

```
## 5. Building the solver and computing the free thermal states
```

The next cell builds the solver and defines ‘thermal_state‘, which runs ‘revision_ks_solver single‘ with ‘--T‘ (the temperature) and ‘--margin 0.2‘ (the label set of the canonical matrix, so that the state is exactly the recorded one), and with ‘--mermin-levels‘, which writes the final levels as decimal numbers that read back into exactly the solver’s numbers. It returns the solver’s μ, its levels with degeneracies, and the full level list (shell, block type, parity, label, energy, degeneracy, occupation). The cell then computes the 18 free states $N = 8, 136$, $a_{4,0} = 0, 1, 2$, $T = 0.01, 0.02, 0.05$, and two more for $N = 136$ at $a_{4,0} = 0.5$ and 1.5 ($T = 0.05$), and compares each μ with the record.

## 6. The chemical potential at 40 digits, and the other functions of state

The next cell solves $\sum g f = N$ again with mpmath at 40 significant digits
(Newton's method started at the solver's $\mu$), so that rounding plays no role at
all. The solver's $\mu$ must lie within its own **rounding bound** (column
`mu_rounding_bound` of the record) of this exact root. Then it computes $E$, $S$,
$F$, $\Omega$, $C_V$ (closed form) and $dN/d\mu$ in double precision at the solver's
$\mu$ and compares them with the record. The record's $C_V$ is a numerical
derivative $T\,dS/dT$ (Richardson differences), so the comparison allows
$10^{-4}$; the others agree to $10^{-12}$.
```

## 7. Why the solver uses a balance instead of the direct count

Near a closed shell at low temperature almost every level is either full ($f
\approx 1$) or empty ($f \approx 0$). The direct count $\sum g f - N$ then adds
numbers close to 1 and subtracts $N$: in double precision the result is a multiple
of the rounding step of $N$ (about $10^{-15}$), while the true value changes with
$\mu$ only at the rate $dN/d\mu$, which for $N = 8$ at $a_{4,0} = 0$,
$T = 0.01$ is about $1.2 \times 10^{-6}$. So the direct count cannot locate $\mu$
better than about $10^{-15}/(1.2 \times 10^{-6})$, a few times $10^{-10}$ to
$10^{-9}$ (the record found an error of $8.3 \times 10^{-10}$ in the solver's
earlier version, which used the direct count). The solver
instead balances the thermal **particles** above the filled levels against the
thermal **holes** below them, $P = \sum_{above} g f(x)$ and $H_l = \sum_{below} g
f(-x)$ (each hole factor computed as $f(-x)$, never as $1 - f$), and solves
$\ln P = \ln H_l$; no large numbers are subtracted. The next cell computes the
direct count in double precision and the exact count at 40 digits at 61 values of
$\mu$ within $\pm 3 \times 10^{-9}$ of the root, and finds the root of the balance
in double precision by bisection down to neighbouring numbers.
```

## 8. The chemical potential as a function of temperature

With ‘balance_root‘ the next cell computes $\mu$ at 49 temperatures from $0.002$ to
$0.05$ for $N = 8$ at $a_{4,0} = 0$, $1$, $2$, using the level set of the solver at
$T = 0.05$ (the largest window; at lower temperatures the extra levels are empty to
far below the rounding). For $a_{4,0} = 0$ the two-level picture explains $\mu$:
the eight zero modes ($\varepsilon = 0$) lose as many particles as the 24 orbitals of
the first band level ($\varepsilon = \Delta = 0.4307$), $8e^{-\mu/T} =
24e^{-(\Delta - \mu)/T}$, so $\mu = \Delta/2 - (T/2)\ln 3$ (the logarithm of the
ratio of degeneracies). The check compares this formula with the record at
$T = 0.01$.

## 10. The heat capacity

The next cell draws $C_V(T)$ (closed form) for $N = 8$ at three slices (left) and
$N = 136$ at five slices (right), on logarithmic vertical axes, with the record's
values. For $N = 8$ at $a_{4,0} = 0$ the gas is **activated**: below $T \approx 0.02$
the heat capacity is tiny, because the first excitation costs the gap $0.43\,m$.
Along the history the gap closes and the heat capacity rises at lower temperatures.
$N = 136$ has a much smaller gap ($0.083\,m$ at $a_{4,0} = 0$, $0.014\,m$ at $2$) and
a large heat capacity already at $T = 0.01$.
```

In [7]:

## 12. The filling convention and its sea holes

The convention fills only the positive branch. The sea's brane band (block type
$j = -1$, even parity, label 0) has, without interaction, exactly the energies
$-\varepsilon_{band}(n_2)$ of the brane band of $j = +1$ (the block Hamiltonians obey
$h_{-1} = -h_{+1}$ when $v = 0$). If the sea were treated thermally, its levels would
carry holes with the probability $1 - f(-\varepsilon_{band}) =
```

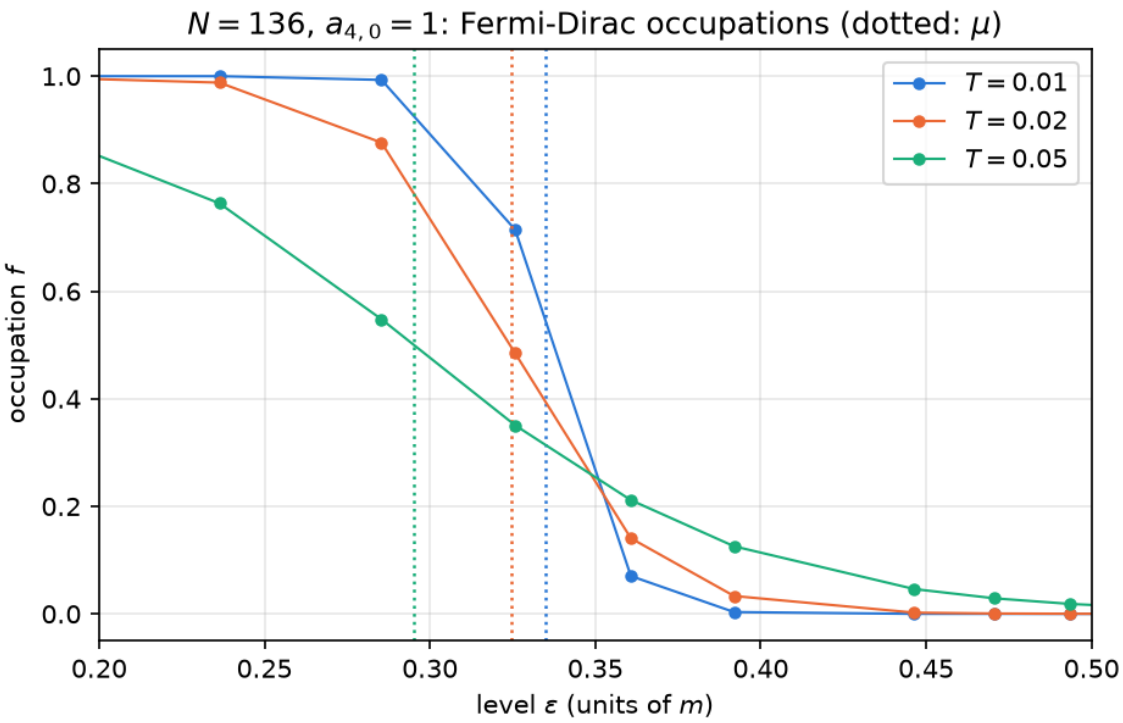

Figure 436: The occupation f of the levels of the free state $N = 136$ at $a_{4,0} = 1$ (vertical axis) against their energy (horizontal axis, units of m, near the Fermi level) at the temperatures $T = 0.01$, 0.02, 0.05; dotted lines: the chemical potentials. The step from full to empty widens with the temperature, over a few T. (Notebook 15d, figure 5.)

```
1/(1 + e^{(\mu + \varepsilon_{band})/T})$. The next cell adds up
$4 r_3(n_2)$ times this probability over the shells $n_2 \ge 1$ of the level set and
compares with the record's column 'sea_holes_excluded' for $N = 8$ at $T = 0.05$. The
figure shows the record's number of sea holes per particle for $N = 8$ and $136$ at
all slices and temperatures: above about 1 percent (dotted line) the particle-only
ensemble is outside its range of validity, and a thermal treatment of the sea
(particle-antiparticle pairs) would be needed.

## 13. The interaction at finite temperature

The last figure uses only the record: the change of the free energy caused by the
couplings $\pm\lambda_1$, $F(\lambda) - F(0)$, for $N = 8$, $136$ and $688$ at the
first slice and the three temperatures. The two checks: the interaction changes $F$
by less than $0.005\,m$; and repulsion ($+\lambda_1$) raises it for $N = 136$ and
$688$ but lowers it for $N = 8$, attraction the other way round (the zero-mode state
$N = 8$ has no scalar density without interaction, so to first order its
interaction energy is the exchange term $-\tfrac{1}{32}\lambda n^2$, negative for
$\lambda > 0$).
```

## 15. What this notebook showed

- From the solver's levels alone, plain Python reproduces the chemical potential,
  energy, entropy, free energy, grand potential, heat capacity and $dN/d\mu$ of the
  free thermal states of the record (COMPUTED).
- The solver's chemical potential lies within its rounding bound of the 40-digit
  root; the direct count in double precision could not do this, which is why the
  solver balances thermal particles against thermal holes.
- $\mu$ starts in the middle of the gap and falls with $T$; along the deflating
  history the gaps close, so the entropy rises, the free energy falls faster and the
  heat capacity rises at lower temperatures; $-dF/dT = S$ holds.
- The particle-only filling is a CONVENTION; late in the history at the higher
  temperatures the excluded sea would carry many holes (up to 31 per particle for
  $N = 8$), and there the convention is outside its range of validity (OPEN: a
  thermal treatment of the sea).
- These are instantaneous states on a PRESCRIBED background, with the brane
  ASSUMED.
```

15.30 Line-by-line walk-through of Notebook 15d

The notebook has 11 code cells, In [1] to In [11]; the complete cells are printed in Section 15.29.

In [1], the set-up cell. It is the set-up cell of Notebook 15a (Section 15.14 for the Rust lines, Section 15.9 for the rest), with the run instructions of this notebook (Section 15.28) in its comments and `NOTEBOOK_ID = "15d"`.

In [2], the solver and the free thermal states.

```
import csv  # reads the tables (CSV files)
import math  # exp, log for single numbers

import mpmath  # numbers with 40 digits
import numpy as np  # arrays of numbers

program = rust_program("Revision/kohn_sham/solver/Cargo.toml", "revision_ks_solver")
RUN_FOLDER = REPO / "Revision/kohn_sham/solver/target/textbook_15d"  # git ignores it
RUN_FOLDER.mkdir(parents=True, exist_ok=True)
```

The imports, among them mpmath, a package for numbers with as many digits as asked for; the solver is built, and the folder `textbook_15d` inside its build folder receives this notebook's runs.

```
PALETTE = ["#2a78d6", "#eb6834", "#1baf7a", "#eda100", "#e87ba4", "#008300",
           "#4a3aa7", "#e34948"]  # the colours of the figures, in a fixed order
SHADES = {0.0: "#86b6ef", 0.5: "#5598e7", 1.0: "#2a78d6", 1.5: "#1c5cab",
          2.0: "#104281"}  # one shade of blue per slice, light to dark
TEMPS = (0.01, 0.02, 0.05)

def state_id(n, a4, t, tag="lam0"):
    return f"N{n}_{tag}_a{round(10 * a4):02d}_T{round(1000 * t)}"
```

The colours, one shade per slice in a dictionary, the three temperatures of the record, and the names of the thermal states, for example `N8_lam0_a00_T10` for $N = 8$, $\lambda = 0$, $a_{4,0} = 0$, $T = 0.01$.

```
def thermal_state(n, a4, t):
    name = state_id(n, a4, t)
    out, lev = RUN_FOLDER / f"{name}.json", RUN_FOLDER / f"{name}-levels.json"
    done = subprocess.run(
        [str(program), "single", "--root", str(REPO), "--m", "1", "--lambda", "0",
         "--a4", repr(a4), "--N", repr(float(n)), "--T", repr(t), "--margin", "0.2",
         "--out", str(out), "--mermin-levels", str(lev)],
        capture_output=True, text=True)
    if done.returncode != 0:
        raise RuntimeError(f"the solver failed for {name}: {done.stderr[-500:]}")
```

`thermal_state` runs `single` for one free thermal state. Compared with Notebook 15b it adds the temperature, the margin 0.2 of the canonical thermal runs (so that the label set, and therefore the state, is exactly the recorded one), and the option that writes the final levels and μ into a second file as decimal numbers that read back into exactly the solver's double-precision numbers.

```
    exact = json.loads(lev.read_text(encoding="utf-8"))
    full = json.loads(out.read_text(encoding="utf-8"))
    eps = [float(e) for e, _ in exact["levels_eps_deg"]]  # exactly the solver's
    deg = [float(g) for _, g in exact["levels_eps_deg"]]
    return float(exact["mu"]), eps, deg, full["levels_n2_j_parity_label_eps_deg_f"]
```

The two files are read; `eps` and `deg` are the levels and their degeneracies, and the function returns the solver's μ, these two lists, and the full level list (shell, block type, parity, label, energy, degeneracy, occupation) from the main JSON file.

```
THERMO = "Revision/kohn_sham/results/thermo/thermodynamics.csv"
with open(repository_file(THERMO), newline="", encoding="utf-8") as handle:
    record = {row["id"]: row for row in csv.DictReader(handle)}
states = {}
for n in (8, 136):
    for a4 in (0.0, 1.0, 2.0):
        for t in TEMPS:
            states[(n, a4, t)] = thermal_state(n, a4, t)
for a4 in (0.5, 1.5):
    states[(136, a4, 0.05)] = thermal_state(136, a4, 0.05)
```

The record's table of the 135 thermal states is read, and 20 free states are computed: $N = 8$ and 136 at the slices 0, 1, 2 and the three temperatures (18 states), and $N = 136$ at $a_{4,0} = 0.5$ and 1.5 with $T = 0.05$.

```
worst_mu = max(abs(mu - float(record[state_id(n, a4, t)]["mu"]))
               for (n, a4, t), (mu, _, _, _) in states.items())
report("free thermal states computed", len(states))
report("largest |mu(solver now) - mu(record)|", f"{worst_mu:.1e}")
check(worst_mu < 1e-12, f"the solver reproduces the recorded mu of {len(states)} states",
      record=f"{THERMO}, column mu")
```

Out [2]: 20 states, and the new μ agrees with the record to 5.6×10^{-17} (the record's column holds 16 significant digits).

In [3], the 40-digit root and the functions of state.

```
def exact_root(eps, deg, n, t, guess):
    with mpmath.workdps(40):
        levels = [(mpmath.mpf(e), mpmath.mpf(g)) for e, g in zip(eps, deg)]
        temp, mu = mpmath.mpf(t), mpmath.mpf(guess)
        for _ in range(60):
            occ = [(g, 1 / (1 + mpmath.exp((e - mu) / temp))) for e, g in levels]
            count = sum(g * f for g, f in occ) - n
            slope = sum(g * f * (1 - f) for g, f in occ) / temp  # dN/dmu
            step = count / slope
            mu -= step
            if abs(step) < mpmath.mpf(10) ** -36:
                break
        return mu
```

`exact_root` solves $\sum gf = N$ with 40 significant digits: inside `with mpmath.workdps(40):` every mpmath number (`mpmath.mpf`) carries 40 digits. Starting at the solver's μ, Newton's method takes the step $(\sum gf - N)/(dN/d\mu)$ with $dN/d\mu = \sum gf(1-f)/T$ (Section 15.26), at most 60 times, until the step is below 10^{-36}. With 40 digits the subtraction of N loses nothing that matters.

```
def functions_of_state(eps, deg, mu, t):
    e, g = np.array(eps), np.array(deg)
    x = (e - mu) / t
    small = np.exp(-np.abs(x))  # e^{-|x|}, never overflows
```

```
    f_abs = small / (1.0 + small)  # f(|x|)
    f = np.where(x > 0, f_abs, 1.0 - f_abs)  # f(x)
    energy = float(np.sum(g * f * e))
```

`functions_of_state` computes the functions of state of a free state in double precision, in forms that never overflow. `small` is $e^{-|x|}$, at most 1; `f_abs` is $f(|x|) = e^{-|x|}/(1+e^{-|x|})$; `np.where(conditi on, a, b)` takes a where the condition holds and b elsewhere, so `f` is $f(x)$ ($f(|x|)$ for $x > 0$ and $1 - f(|x|)$ otherwise). The energy is $\sum gf\varepsilon$ (no interaction).

```
    # -[f ln f + (1-f) ln(1-f)] = ln(1 + e^{-|x|}) + |x| f(|x|)
    entropy = float(np.sum(g * (np.log1p(small) + np.abs(x) * f_abs)))
    # ln(1 + e^{-x}) = max(-x, 0) + ln(1 + e^{-|x|})
    omega = -t * float(np.sum(g * (np.maximum(-x, 0.0) + np.log1p(small))))
```

The two comment lines state the formulas that the next lines use. The entropy of one level is $-[f \ln f + (1-f)\ln(1-f)] = \ln(1+e^{-|x|}) + |x|\, f(|x|)$. (For $x \geq 0$: $\ln f = -x - \ln(1+e^{-x})$ and $\ln(1-f) = -\ln(1+e^{-x})$; inserting, the two logarithms add to $\ln(1+e^{-x})$ and the rest is xf; for $x < 0$ the roles of f and $1-f$ exchange.) `np.log1p(s)` is $\ln(1+s)$, accurate also for tiny s. The grand potential uses $\ln(1+e^{-x}) = \max(-x, 0) + \ln(1+e^{-|x|})$.

```
    w = g * f_abs * (1.0 - f_abs)  # g f (1 - f), the same for x and -x
    d = e - mu
    cv = float((np.sum(w * d * d) - np.sum(w * d) ** 2 / np.sum(w)) / t ** 2)
    return energy, entropy, energy - t * entropy, omega, cv, float(np.sum(w) / t)
```

`w` is $w_i = g_i f_i (1 - f_i)$ (the product $f(1-f)$ is the same for x and $-x$), `cv` the closed form of C_V derived in Section 15.26, and the function returns E, S, $F = E - TS$, Ω, C_V and $dN/d\mu = \sum w/T$.

```
rel = lambda a, b: abs(a - b) / max(abs(b), 1.0)  # relative to max(|b|, 1)
worst = {"root": 0.0, "E S F Omega": 0.0, "C_V": 0.0, "dN/dmu": 0.0}
for (n, a4, t), (mu, eps, deg, _) in states.items():
    row = record[state_id(n, a4, t)]
    root = exact_root(eps, deg, n, t, mu)
    worst["root"] = max(worst["root"],
                        float(abs(mu - root)) / float(row["mu_rounding_bound"]))
    e_, s_, f_, o_, cv, dn = functions_of_state(eps, deg, mu, t)
    worst["E S F Omega"] = max(worst["E S F Omega"], rel(e_, float(row["E"])),
                               rel(s_, float(row["entropy"])), rel(f_, float(row["F"])),
                               rel(o_, float(row["Omega_direct"])))
    worst["C_V"] = max(worst["C_V"], abs(cv / float(row["C_V"]) - 1.0))
    worst["dN/dmu"] = max(worst["dN/dmu"], abs(dn / float(row["dN_dmu"]) - 1.0))
```

For each of the 20 states: the 40-digit root, the distance of the solver's μ from it measured in units of the recorded rounding bound (column `mu_rounding_bound`, the solver's first-order estimate of the rounding error of its root), and the functions of state compared with the record's columns (relative to the larger of the value and 1). The dictionary `worst` keeps the largest deviation of each kind.

```
report("largest |mu - 40-digit root| / recorded rounding bound", f"{worst['root']:.2f}")
for key in ("E S F Omega", "C_V", "dN/dmu"):
```

```
    report(f"largest relative difference, {key}", f"{worst[key]:.1e}")
check(worst["root"] <= 1.0, "mu lies within its rounding bound of the 40-digit root",
      record="Revision/kohn_sham/reports/ks-rust-mermin-roots.json and "
             f"{THERMO}, column mu_rounding_bound")
check(worst["E S F Omega"] < 1e-12,
      f"E, S, F and Omega of {len(states)} states reproduced",
      record=f"{THERMO}, columns E, entropy, F, Omega_direct")
check(worst["C_V"] < 1e-4, "the closed-form C_V reproduces the recorded T dS/dT",
      record=f"{THERMO}, column C_V")
check(worst["dN/dmu"] < 1e-9, "dN/dmu reproduced", record=f"{THERMO}, column dN_dmu")
```

Out [3]: μ lies within 0.07 of its rounding bound of the exact root; E, S, F, Ω agree to 3.6×10^{-14}; the closed-form C_V agrees with the record's Richardson difference $T\,dS/dT$ to 1.6×10^{-5} (the accuracy of the difference quotient); $dN/d\mu$ to 2.0×10^{-15}. All four checks pass.

In [4], why the balance is needed.

```
def balance_root(eps, deg, n, t):
    order = np.argsort(eps, kind="stable")
    e, g = np.array(eps)[order], np.array(deg)[order]
    filled = int(np.searchsorted(np.cumsum(g), n - 1e-9)) + 1  # T = 0 filling
    below_e, below_g, above_e, above_g = e[:filled], g[:filled], e[filled:], g[filled:]
```

`balance_root` finds μ from the balance of Section 15.26 in double precision. The levels are sorted by energy (`np.argsort` gives the order; `kind="stable"` keeps equal levels in their original order). `np.cumsum(g)` is the running total of the degeneracies, and `np.searchsorted` finds the position where it reaches N; the first `filled` levels are the set $\mathcal{S}$ filled at $T = 0$ (the states here are closed shells, so $d = 0$).

```
    def log_sum(log_terms):  # ln(sum e^{t}) without overflow or underflow
        top = float(np.max(log_terms))
        return top + math.log(float(np.sum(np.exp(log_terms - top))))

    def log_f(x):  # ln f(x) = -ln(1 + e^{x}), stable for every x
        return -(np.maximum(x, 0.0) + np.log1p(np.exp(-np.abs(x))))
```

`log_sum` is the log-sum-exp $\ln \sum e^{t_i} = t_{max} + \ln \sum e^{t_i - t_{max}}$, in which every exponential is at most 1. `log_f` is $\ln f(x) = -\ln(1 + e^x) = -[\max(x, 0) + \ln(1 + e^{-|x|})]$, which works for every x, however large.

```
    def balance(mu):
        return (log_sum(np.log(above_g) + log_f((above_e - mu) / t))
                - log_sum(np.log(below_g) + log_f(-(below_e - mu) / t)))

    lo, hi = float(e[0]) - 1.0, float(e[-1]) + 1.0
    while lo < 0.5 * (lo + hi) < hi:  # bisection down to neighbouring numbers
        mid = 0.5 * (lo + hi)
        lo, hi = (mid, hi) if balance(mid) < 0.0 else (lo, mid)
    return lo
```

`balance(mu)` is $\ln P - \ln H_l$: each term $g\,f$ is written as $e^{\ln g + \ln f}$, so that $\ln P$ = log-sum-exp of $\ln g + \ln f(x)$ over the levels above, and $\ln H_l$ the same with $f(-x)$ over the levels below. It increases with μ (more particles above, fewer holes below). Bisection between a value below all levels and one above them halves the interval until its midpoint is no longer strictly between its ends, that is, until `lo` and `hi` are neighbouring double-precision numbers.

```
mu8, eps8, deg8, _ = states[(8, 0.0, 0.01)]
root8 = exact_root(eps8, deg8, 8, 0.01, mu8)
offsets = np.linspace(-3e-9, 3e-9, 61)
direct, exact = [], []
for off in offsets:
    x = (np.array(eps8) - (mu8 + off)) / 0.01
    direct.append(float(np.sum(np.array(deg8) / (1.0 + np.exp(x)))) - 8.0)
    with mpmath.workdps(40):
        m_ = mpmath.mpf(mu8) + mpmath.mpf(off)
        exact.append(float(sum(mpmath.mpf(g) / (1 + mpmath.exp((mpmath.mpf(e) - m_)
                                                               / mpmath.mpf(0.01)))
                               for e, g in zip(eps8, deg8)) - 8))
```

For the activated state $N = 8$, $a_{4,0} = 0$, $T = 0.01$ the cell evaluates the count $\sum g f - 8$ at 61 values of μ within $\pm 3 \times 10^{-9}$ of the solver's μ: once directly in double precision (`direct`) and once with 40 digits (`exact`).

```
fig, ax = plt.subplots()
ax.plot(offsets * 1e9, direct, "s-", color=PALETTE[1], ms=4, lw=1.2,
        label="direct count, double precision")
ax.plot(offsets * 1e9, exact, color=PALETTE[0], lw=2.0, label="exact count, 40 digits")
ax.axvline(float(root8 - mu8) * 1e9, color="0.3", ls=":", lw=1.2, label="exact root")
ax.axhline(0.0, color="0.6", lw=0.8)
ax.set_xlabel("$\\mu$ minus the solver's $\\mu$ (units of $10^{-9}\\,m$)")
ax.set_ylabel("$\\sum g f - N$")
ax.set_title("$N = 8$, $a_{4,0} = 0$, $T = 0.01$: the direct count is too coarse")
ax.legend(fontsize=8)
```

Both counts are drawn against the offset in units of 10^{-9}, with the exact root as a dotted vertical line and a zero line.

```
zero_at = [off for off, value in zip(offsets, direct) if value == 0.0]  # direct = 0
if zero_at:  # where the double-precision count says "exactly N particles"
    miss = min(abs(off - float(root8 - mu8)) for off in zero_at)  # nearest such point
    where = ("is zero only on a short interval that misses the true root by at "
             f"least ${miss * 1e10:.0f} \\times 10^{{-10}}\\,m$")
    report("distance of the zeros of the direct count from the true root",
           f"at least {miss:.1e} m")
else:  # (on another computer the rounding steps may fall differently)
    where = "is never exactly zero at the sampled points"
save_figure(fig, "root_conditioning",
            "The particle-number condition $\\sum g f - N$ (vertical axis, of size "
...)
```

`zero_at` collects the sampled values of μ at which the double-precision count is exactly zero; `miss` is the smallest distance of such a point from the true root. The caption of Figure 15d.1 is completed with a sentence that depends on what was found (on another computer the rounding steps may fall differently). Out [4] reports that these zeros miss the true root by at least $3.0 \times 10^{-10}\,m$.

```
worst_balance = 0.0
for (n, a4, t), (mu, eps, deg, _) in states.items():
    root = exact_root(eps, deg, n, t, mu)
    worst_balance = max(worst_balance, float(abs(balance_root(eps, deg, n, t) - root)))
zero_width = (np.sum(np.array(direct) == 0.0)) * (offsets[1] - offsets[0])
report("width of the interval where the double-precision direct count is 0",
       f"{zero_width:.1e} m")
report(f"largest |balance root - 40-digit root| ({len(states)} states)",
       f"{worst_balance:.1e}")
check(worst_balance < 1e-15, "the double-precision balance finds mu to 1e-15",
      record="Revision/kohn_sham/reports/ks-rust-solver.json, check "
             "thermo_mu_well_conditioned_root")
```

For all 20 states the root of the balance is compared with the 40-digit root, and the width of the interval where the direct count is zero is estimated from the number of sampled zeros times the spacing. Out [4]: the width is $3.0 \times 10^{-10}\,m$, while the balance finds every root to $9.3 \times 10^{-17}\,m$, about three million times better. In Figure 15d.1 the orange squares jump in steps of the rounding unit of N (size 10^{-15}) while the blue line crosses zero at one point.

In [5], the chemical potential against the temperature.

```
T_GRID = np.linspace(0.002, 0.05, 49)

def curves(n, a4):
    _, eps, deg, _ = states[(n, a4, 0.05)]
    rows = []
    for t in T_GRID:
        mu = balance_root(eps, deg, n, t)
        energy, entropy, free, _, cv, _ = functions_of_state(eps, deg, mu, t)
        rows.append((mu, energy, entropy, free, cv))
    return np.array(rows)  # columns: mu, E, S, F, C_V
```

`T_GRID` holds 49 temperatures from 0.002 to 0.05. `curves` takes the levels of the state at $T = 0.05$ (the largest thermal window; at lower temperatures the extra levels are empty far below the rounding) and computes μ, E, S, F and C_V at every temperature of the grid, returned as an array with one row per temperature.

```
GROUND = "Revision/kohn_sham/results/ground/summary.csv"
with open(repository_file(GROUND), newline="", encoding="utf-8") as handle:
    ground = {row["id"]: row for row in csv.DictReader(handle)}
gap8 = float(ground["N8_lam0_a00"]["KS_gap"])
two_level = gap8 / 2.0 - 0.5 * T_GRID * math.log(3.0)
curve8 = {a4: curves(8, a4) for a4 in (0.0, 1.0, 2.0)}
```

The gap $\Delta = 0.4307337$ of `N8_lam0_a00` is read from the record's ground-state table, the two-level formula $\Delta/2 - (T/2)\ln 3$ of Section 15.26 is evaluated on the grid, and the curves of $N = 8$ are computed at three slices.

```
fig, ax = plt.subplots()
for a4 in (0.0, 1.0, 2.0):
    ax.plot(T_GRID, curve8[a4][:, 0], color=SHADES[a4], lw=2.0,
            label=f"$a_{{4,0}} = {a4:.0f}$")
    ax.plot(TEMPS, [float(record[state_id(8, a4, t)]["mu"]) for t in TEMPS], "o",
            color=SHADES[a4], ms=8, markerfacecolor="white")
ax.plot(T_GRID, two_level, "--", color=PALETTE[1], lw=1.5,
        label="$\\Delta/2 - (T/2)\\ln 3$, $a_{4,0} = 0$")
ax.plot([], [], "o", color="0.4", markerfacecolor="white", label="record")
ax.set_xlabel("temperature $T$ (units of $m$)")
ax.set_ylabel("chemical potential $\\mu$ (units of $m$)")
ax.set_title("$N = 8$, $\\lambda = 0$: the chemical potential")
ax.legend(fontsize=8)
save_figure(fig, "chemical_potential",
            "The chemical potential $\\mu$ (vertical axis, units of $m$) of the free "
...)
```

$\mu(T)$ at the three slices (`curve8[a4][:, 0]` is the first column of the array), the record's values as open circles, and the two-level formula dashed; then Figure 15d.2.

```
formula = gap8 / 2.0 - 0.005 * math.log(3.0)
recorded = float(record[state_id(8, 0.0, 0.01)]["mu"])
report("mu of N8_lam0_a00_T10: two-level formula / record",
       f"{formula:.12f} / {recorded:.12f}")
check(abs(formula - recorded) < 1e-8, "the two-level formula gives mu to 1e-8",
      record=f"{THERMO}, N8_lam0_a00_T10")
```

The formula at $T = 0.01$ ($T/2 = 0.005$): 0.209873777875 against the record's 0.209873776387 (Out [5]); the check passes. In the figure, μ starts at $\Delta/2$ and falls along the dashed line; at the later slices the gap and with it μ are smaller.

In [6], free energy and entropy.

```
curve136 = {a4: curves(136, a4) for a4 in (0.0, 0.5, 1.0, 1.5, 2.0)}
fig, (left, right) = plt.subplots(1, 2, figsize=(10.0, 4.0), layout="constrained")
for a4, values in curve136.items():
    e0 = float(ground[f"N136_lam0_a{round(10 * a4):02d}"]["E_KS"])
    left.plot(T_GRID, values[:, 3] - e0, color=SHADES[a4], lw=2.0,
              label=f"$a_{{4,0}} = {a4}$")
    right.plot(T_GRID, values[:, 2], color=SHADES[a4], lw=2.0)
```

The curves of $N = 136$ at the five slices; on the left the free energy measured from the ground-state energy E_0 of the same slice (column 3 of the curves minus `e0`), on the right the entropy (column 2).

```
    if a4 in (0.0, 1.0, 2.0):
        ids = [state_id(136, a4, t) for t in TEMPS]
```

```
        left.plot(TEMPS, [float(record[i]["F"]) - e0 for i in ids], "o",
                  color=SHADES[a4], ms=7, markerfacecolor="white")
        right.plot(TEMPS, [float(record[i]["entropy"]) for i in ids], "o",
                   color=SHADES[a4], ms=7, markerfacecolor="white")
left.set_xlabel("temperature $T$")
left.set_ylabel("$F - E_0$ (units of $m$)")
left.set_title("Free energy, $N = 136$, $\\lambda = 0$")
left.legend(fontsize=8)
right.set_xlabel("temperature $T$")
right.set_ylabel("entropy $S$")
right.set_title("Entropy (circles: record)")
save_figure(fig, "free_energy_entropy",
            "Left: the free energy measured from the ground-state energy, "
...)
```

Where the record has thermal states (slices 0, 1, 2), its values are drawn as open circles; then the labels and Figure 15d.3.

```
_, eps, deg, _ = states[(136, 1.0, 0.05)]
worst_fs = 0.0
for t in T_GRID:
    h = 1e-3 * t
    f_plus = functions_of_state(eps, deg, balance_root(eps, deg, 136, t + h), t + h)[2]
    f_minus = functions_of_state(eps, deg, balance_root(eps, deg, 136, t - h), t - h)[2]
    s = functions_of_state(eps, deg, balance_root(eps, deg, 136, t), t)[1]
    worst_fs = max(worst_fs, abs(-(f_plus - f_minus) / (2 * h) - s) / s)
```

The identity $-dF/dT = S$ of Section 15.26 is tested for $N = 136$ at $a_{4,0} = 1$ at every temperature of the grid: the central difference $[F(T+h) - F(T-h)]/(2h)$ with $h = 10^{-3}T$ (each F at its own μ; index 2 of the returned tuple is F, index 1 is S) is compared with S.

```
report("largest relative |-dF/dT - S|, N = 136, a4,0 = 1", f"{worst_fs:.1e}")
check(worst_fs < 1e-4, "-dF/dT = S along the whole temperature grid",
      record="Revision/kohn_sham/reports/ks-rust-solver.json, check "
             "thermo_entropy_identity")
rising = all(bool(np.all(np.diff(v[:, 2]) > 0)) and bool(np.all(np.diff(v[:, 3]) < 0))
             for v in curve136.values())
check(rising, "S rises and F falls with T at every slice")
```

Out [6]: the largest relative deviation is 7.5×10^{-6}; and at every slice S rises and F falls with T at every step of the grid. In Figure 15d.3 the later slices (darker) have the larger entropy at the same temperature: the history crowds the levels together, so the same temperature excites more particles.

In [7], the heat capacity.

```
fig, (left, right) = plt.subplots(1, 2, figsize=(10.0, 4.0), layout="constrained")
for a4, values in curve8.items():
    left.plot(T_GRID, values[:, 4], color=SHADES[a4], lw=2.0,
              label=f"$a_{{4,0}} = {a4:.0f}$")
    left.plot(TEMPS, [float(record[state_id(8, a4, t)]["C_V"]) for t in TEMPS], "o",
```

```
            color=SHADES[a4], ms=7, markerfacecolor="white")
for a4, values in curve136.items():
    right.plot(T_GRID, values[:, 4], color=SHADES[a4], lw=2.0,
               label=f"$a_{{4,0}} = {a4}$")
    if a4 in (0.0, 1.0, 2.0):
        right.plot(TEMPS, [float(record[state_id(136, a4, t)]["C_V"]) for t in TEMPS],
                   "o", color=SHADES[a4], ms=7, markerfacecolor="white")
```

The closed-form C_V (column 4 of the curves) of $N = 8$ at three slices on the left and of $N = 136$ at five slices on the right, with the record's values as circles.

```
for ax, n in ((left, 8), (right, 136)):
    ax.set_yscale("log")
    ax.set_xlabel("temperature $T$ (units of $m$)")
    ax.set_title(f"Heat capacity, $N = {n}$, $\\lambda = 0$")
    ax.legend(fontsize=8)
left.set_ylabel("$C_V$ (pure number)")
save_figure(fig, "heat_capacity",
            "The heat capacity $C_V = dE/dT$ (vertical axis, logarithmic, pure "
...)
positive = all(bool(np.all(v[:, 4] > 0)) for v in list(curve8.values())
               + list(curve136.values()))
check(positive, "C_V > 0 at every temperature and slice")
```

Both panels get a logarithmic axis, labels and a legend; Figure 15d.4; and the check that C_V is positive everywhere (the closed form is a weighted variance of the d_i divided by T^2, so it cannot be negative). In the figure the gas $N = 8$ at $a_{4,0} = 0$ is **activated**: its heat capacity is tiny below $T \approx 0.02$, because each excitation costs the gap $0.43\,m$ and is suppressed like $e^{-\Delta/(2T)}$; as the history closes the gap, the heat capacity wakes up at ever lower temperatures. $N = 136$, with its much smaller gap, has a large heat capacity already at $T = 0.01$.

In [8], the occupations.

```
fig, ax = plt.subplots()
sums = []
for colour, t in zip(PALETTE, TEMPS):
    mu, eps, deg, levels = states[(136, 1.0, t)]
    e = np.array(eps)
    f = 1.0 / (1.0 + np.exp(np.minimum((e - mu) / t, 700.0)))
    sums.append(float(np.sum(np.array(deg) * f)))
    order = np.argsort(e)
    ax.plot(e[order], f[order], "o-", color=colour, ms=4, lw=1.0, label=f"$T = {t}$")
    ax.axvline(mu, color=colour, ls=":", lw=1.2)
```

For $N = 136$ at $a_{4,0} = 1$ and the three temperatures the occupation f of every level is computed (`np.minimum(..., 700.0)` caps the exponent, because e^{710} would overflow), the sum $\sum g f$ is kept, and f is drawn against the level, sorted by energy, with μ as a dotted vertical line.

```
ax.set_xlim(0.2, 0.5)
ax.set_xlabel("level $\\varepsilon$ (units of $m$)")
```

```
ax.set_ylabel("occupation $f$")
ax.set_title("$N = 136$, $a_{4,0} = 1$: Fermi-Dirac occupations (dotted: $\\mu$)")
ax.legend()
save_figure(fig, "occupations",
            "The occupation $f$ of the levels of the free state $N = 136$ at "
...)
report("sum g f at the three temperatures", ", ".join(f"{s:.12f}" for s in sums))
check(max(abs(s - 136.0) for s in sums) < 1e-9, "the occupations add up to N = 136",
      record="Revision/kohn_sham/reports/ks-rust-solver.json, check "
             "thermo_N_conservation")
```

The horizontal range is limited to the levels near the Fermi level (0.2 to 0.5); Figure 15d.5; Out [8]: the sums are 136.000000000000 at all three temperatures. In the figure the step from full to empty widens with T.

In [9], the sea holes.

```
def shell_sizes(largest):
    reach = math.isqrt(largest) + 1
    sizes = {}
    for x in range(-reach, reach + 1):
        for y in range(-reach, reach + 1):
            for z in range(-reach, reach + 1):
                s = x * x + y * y + z * z
                if s <= largest:
                    sizes[s] = sizes.get(s, 0) + 1
    return sizes
```

`shell_sizes` counts $r_3(n_2)$ for all n_2 up to `largest` by brute force: it visits every vector of whole numbers in a cube large enough (`math.isqrt` is the whole-number square root) and adds one to the count of its $n_2 = x^2 + y^2 + z^2$.

```
worst_sea, mine = 0.0, {}
for a4 in (0.0, 1.0, 2.0):
    mu, _, _, levels = states[(8, a4, 0.05)]
    band = {lv[0]: lv[4] for lv in levels
            if lv[1] == 1 and lv[2] == "even" and lv[3] == 0 and lv[0] >= 1}
    sizes = shell_sizes(max(lv[0] for lv in levels))
    holes = sum(4 * sizes[n2] / (1.0 + math.exp((mu + band[n2]) / 0.05))
                for n2 in sizes if n2 >= 1)
    mine[a4] = holes / 8.0
    recorded = float(record[state_id(8, a4, 0.05)]["sea_holes_excluded"])
    worst_sea = max(worst_sea, abs(holes / recorded - 1.0))
```

For $N = 8$ at $T = 0.05$ and three slices: `band` maps each shell $n_2 \geq 1$ to its band level ($j = +1$, even, label 0; `lv[4]` is the energy in the full level list), the shell sizes are counted up to the largest shell of the level set, and the number of sea holes is $\sum 4 r_3(n_2)/(1 + e^{(\mu+\varepsilon_{band})/T})$ over these shells (Section 15.26). It is divided by 8 for the holes per particle and compared with the record's column `sea_holes_excluded`.

```
fig, ax = plt.subplots()
plotted = []  # every value drawn, to measure their range
for marker, n in (("o", 8), ("s", 136)):
    for colour, t in zip(PALETTE, TEMPS):
        values = [float(record[state_id(n, a, t)]["sea_holes_over_N"])
                  for a in (0.0, 0.5, 1.0, 1.5, 2.0)]
        plotted += values
        ax.plot([0, 0.5, 1, 1.5, 2], np.maximum(values, 1e-60), marker + "-",
                color=colour, ms=6, lw=1.2,
                markerfacecolor=colour if n == 8 else "white",
                label=f"$N = {n}$, $T = {t}$")
```

The record's holes per particle for $N = 8$ (filled circles) and $N = 136$ (open squares), the three temperatures and the five slices, joined by lines; values below 10^{-60} would be drawn at 10^{-60} (the smallest recorded value is about 2×10^{-56}, so none is clipped).

```
ax.plot(list(mine), list(mine.values()), "x", color="black", ms=11, mew=2,
        label="this notebook, $N = 8$, $T = 0.05$")
ax.axhline(0.01, color="0.3", ls=":", lw=1.2, label="1 percent")
ax.set_yscale("log")
ax.set_ylim(1e-60, 1e4)  # the smallest recorded value is about 2e-56
ax.set_xlabel("slice $a_{4,0}$")
ax.set_ylabel("sea holes per particle")
ax.set_title("Diagnostic of the filling convention ($\\lambda = 0$)")
ax.legend(fontsize=7, ncol=2, loc="lower right")
smallest = min(v for v in plotted if v > 0.0)  # the smallest nonzero value
powers = int(math.log10(max(plotted) / smallest))  # whole powers of ten spanned
save_figure(fig, "sea_holes",
            "The number of thermal holes that the excluded sea brane band would "
...)
```

This notebook's three values as black crosses (`list(mine)` is the list of the slices, the keys of the dictionary), the 1 per cent line, the axes, and the number of whole powers of ten between the smallest and the largest value, which the caption of Figure 15d.6 prints.

```
report("smallest and largest sea holes per particle drawn",
       f"{smallest:.2e}, {max(plotted):.2e}")
report("sea holes per particle, N = 8, T = 0.05, a4,0 = 0, 1, 2",
       ", ".join(f"{v:.4g}" for v in mine.values()))
check(worst_sea < 1e-9, "the sea-hole diagnostic reproduced",
      record=f"{THERMO}, column sea_holes_excluded")
```

Out [9]: the values drawn span from 2.10×10^{-56} to 30.8 holes per particle (57 powers of ten); for $N = 8$ at $T = 0.05$ they are 1.464×10^{-5}, 0.09746 and 30.8 at the slices 0, 1, 2; the record is reproduced. At $a_{4,0} = 2$ the excluded sea would carry about 31 holes for each particle: there the CONVENTION is outside its range of validity.

In [10], the interaction at a temperature.

```
fig, ax = plt.subplots()
shifts = []
```

```
by_series = {}  # (N, tag) -> the three values of F(lambda) - F(0)
for colour, n in zip(PALETTE, (8, 136, 688)):
    for tag, style in (("lamp1", "-"), ("lamm1", "--")):
        values = [float(record[state_id(n, 0.0, t, tag)]["F"])
                  - float(record[state_id(n, 0.0, t)]["F"]) for t in TEMPS]
        shifts += values
        by_series[(n, tag)] = values
        sign = "+" if tag == "lamp1" else "-"
        ax.plot(TEMPS, values, style, marker="o", color=colour, ms=6, lw=1.5,
                label=f"$N = {n}$, ${sign}\\lambda_1$")
```

From the record alone: the change $F(\lambda) - F(0)$ of the free energy for $\pm\lambda_1$, $N = 8, 136, 688$, at $a_{4,0} = 0$ and the three temperatures, drawn solid for $+\lambda_1$ and dashed for $-\lambda_1$, and kept in `shifts` and, by series, in `by_series`.

```
ax.set_yscale("symlog", linthresh=1e-4)
ax.axhline(0.0, color="0.5", lw=0.8)
ax.set_xlabel("temperature $T$ (units of $m$)")
ax.set_ylabel("$F(\\lambda) - F(0)$ (units of $m$)")
ax.set_title("Effect of the interaction on the free energy, $a_{4,0} = 0$")
ax.legend(fontsize=8, ncol=2)
up = by_series[(688, "lamp1")]  # N = 688, +lambda_1, at T = 0.01, 0.02, 0.05
save_figure(fig, "interaction_free_energy",
            "The change of the free energy caused by the couplings $+\\lambda_1$ "
...)
```

A symmetric logarithmic axis (linear between -10^{-4} and 10^{-4}), the zero line, labels, and Figure 15d.7, whose caption prints the values of `up`, 0.0033 and $0.0045\,m$ at $T = 0.01$ and 0.05.

```
report("largest |F(lambda) - F(0)| at a4,0 = 0", f"{max(abs(s) for s in shifts):.4f}")
check(max(abs(s) for s in shifts) < 0.005,
      "the interaction changes F by less than 0.005 at a4,0 = 0",
      record=f"{THERMO}, column F")
raises = all(v > 0.0 for n in (136, 688) for v in by_series[(n, "lamp1")]) and all(
    v < 0.0 for n in (136, 688) for v in by_series[(n, "lamm1")])
lowers8 = all(v < 0.0 for v in by_series[(8, "lamp1")]) and all(
    v > 0.0 for v in by_series[(8, "lamm1")])
check(raises and lowers8,
      "repulsion raises F for N = 136 and 688 and lowers it for N = 8",
      record=f"{THERMO}, column F")
```

Out [10]: the largest change is $0.0046\,m$; repulsion raises F for $N = 136$ and 688 and lowers it for $N = 8$, whose zero modes have no scalar density without interaction, so that to first order only the exchange term $-\frac{1}{32}\lambda n^2$ acts (Section 15.5 gives the exact symmetry at $T = 0$).

In [11], the last check.

```
NAMES = ["root_conditioning", "chemical_potential", "free_energy_entropy",
         "heat_capacity", "occupations", "sea_holes", "interaction_free_energy"]
missing = [name for number, name in enumerate(NAMES, start=1)
```

```
        if not output_file(f"{FIGURE_FOLDER}/15d_{number}_{name}.png").is_file()]
check(missing == [], "every figure file of this notebook exists")
all_checks_passed()
```

As in Notebook 15e (Section 15.9, In [15]), with the seven figure names of this notebook in order and the file names `15d_<number>_<name>.png`: the names whose file does not exist are collected, the check requires that list to be empty, and `all_checks_passed()` prints the last line, ALL 15 CHECKS PASSED (notebook 15d).

15.31 What we proved, what we computed, what we assumed

PROVED (exact statements; derived line by line in this chapter or in Chapter 14, and verified by sympy in `Revision/kohn_sham/reports/ks-theory-python.json` and by WolframScript in `Revision/kohn_sham/reports/ks-theory-wolfram.json`):

statement	where	record check
the real block equation, its boundary conditions, self-adjointness, real levels	Section 15.2	`block_hamiltonian`, `bc_brane_parity_conditions`, `bc_self_adjoint_boundary_term`
the Pruefer phase increases strictly and runs over all values: every level has its own label, none is missed	Section 15.3	derived here; the solver's check `free_particle_branch_labels`
the exact levels at $k = 0$ and the zero mode $\sqrt{2M/(1 - e^{-2ML})}\, e^{My}$	Section 15.3	`bc_exact_k0_spectra`
the Hermite midpoint formula and the Anderson weights	Sections 15.3, 15.5	derived here
the brane-band slope $c = 2/(1 + e^{-3}) = 1.9051482536$ (times $e^{-a_{4,0}}$)	Section 15.4	`brane_band_slope`
the rescaling identity: a later slice is the first slice with redshifted momenta	Section 15.4	`rescaling_identity`
$E_{KS} = \sum gf\varepsilon - 2\,\mathrm{Vol}_7 \int e^{6Hy} e_{int}\, dy$ (double counting)	Section 15.5	`ks_onshell_lagrangian`
$E_{KS}(-\lambda) = -E_{KS}(\lambda)$ for the mapped zero-mode state of $N = 8$	Section 15.5	derived here

statement	where	record check
the Hellmann-Feynman theorem and the first-order estimate Q_{nm}	Section 15.21	`adiabatic_hellmann_feynman`, `adiabatic_offdiagonal_identity`
the closed form of C_V, $C_V = T\,dS/dT$, $-dF/dT = S$, $\Omega = F - \mu N$, the balance form of $\sum gf = N$	Section 15.26, Exercise 5	derived here

COMPUTED (numerical, with the record file and the measured agreement):

- The canonical matrix: 75 ground states and 135 thermal states, every one of the 42 checks of `Revision/kohn_sham/reports/ks-rust-solver.json` PASS; a repeat run byte-identical and a refined run within tolerances fixed in advance (`Revision/kohn_sham/reports/ks-rust-determinism.json`, 14 checks PASS); every chemical potential within its rounding bound of a 40-digit root (`Revision/kohn_sham/reports/ks-rust-mermin-roots.json`). Notebook 15a reran the matrix and found every compared number equal to the record (Out [5], Out [6]).

- The method by hand (Notebook 15e): the exact $k = 0$ levels to 7.2×10^{-10}, the solver's levels to 8×10^{-15}, the RK4 error ratio 16.00, the band slope at three slices, and the interacting $N = 8$ states to 10^{-14}.

- Along the history: the $k = 0$ levels do not move, the band levels and all gaps fall (the gap of $N = 8$: 0.4307337, 0.1703493, 0.0641594 at $a_{4,0} = 0, 1, 2$), the energy of the free gas falls ($N = 136$: 80.28 to 12.45), and the integrated ratio $\int p_3 / \int \rho$ rises toward 1/3 (0.2966 to 0.3264).

- Delta-SCF equals the gap without interaction (2.0×10^{-11}); the orbital relaxation is at most $5.5 \times 10^{-4}\,m$; the self-consistent loops converge in at most 17 iterations.

- The conservation law and the energy-change law hold numerically in every state (solver checks `emt_y_conservation_pointwise`, `emt_y_conservation_integrated` and `emt_energy_change_dE_da4`; Notebook 15b).

- $Q_{max} \leq 0.0935$ over the matrix (transition probability below 0.009), no Fermi-level crossing in the matrix, and the demonstration $N = 696$ where the instantaneous ground state is wrong by 3.66 to $8.62\,m$ (Notebook 15c).

- The thermodynamics of the free states from the levels alone (Notebook 15d), and the sea-hole diagnostic: more than 1 per cent of N in 15 of the 135 thermal states, at most $30.98\,N$.

- The dependence on the cutoff from $L = 3$ to 6 of 29 recorded states (`Revision/kohn_sham/tip_convergence/tip-convergence.json`, 7 of 7 checks PASS; Section 15.2): the free results with $k \neq 0$ converge faster than exponentially, the levels at $k = 0$ only like $1/L^2$, and the interacting $N = 8$ energy ($\lambda = \pm\lambda_1$) goes from $\mp 9.868 \times 10^{-4}$ at $L = 3$ to $\mp 3.0046 \times 10^{-3}$ at large L. These are numbers of the record; the notebooks of this chapter compute at $L = 3$ only.

- The five notebooks print 88 PASS lines together (25, 18, 12, 15 and 18).

ASSUMED:

- the good sector (no dependence on the extra times) and the Z2 mirror brane at $y = 0$;
- CHOSEN: the regular tip $b(-L) = 0$ at the cutoff $L = 3$. Its effect is COMPUTED in the record (`Revision/kohn_sham/tip_convergence/`, $L = 3$ to 6, 7 of 7 checks PASS; Section 15.2, the paragraph on the cutoff): the recorded free results, except $N = 688$ at $a_{4,0} = 0$, lie within 1.4 per cent (E_{KS}) and 12 per cent (the integral of p_0) of their large-L values; the interaction effects do not, because the proper zero-mode density grows toward the tip like $e^{(6H-2m)|y|}$: the recorded $N = 8$ interaction energy $\mp 9.868 \times 10^{-4}$ ($\lambda = \pm\lambda_1$) is about one third of its large-L value $\mp 3.0046 \times 10^{-3}$, the interaction shift of $N = 136$ at $a_{4,0} = 2$ is about 21 times its $L = 3$ value at large L ($-\lambda_1$) and about 28 times at $L = 5.5$ ($+\lambda_1$, limit not established), and the self-consistent iteration fails at some larger L for 13 of the 19 interacting states studied. The couplings (calibrated at $L = 3$; the same rule at larger L drives λ_1 to zero) and $N = 688$ (bulk edge at $L = 3$) are themselves choices at $L = 3$;
- CONVENTION: particles fill the positive branch and the zero modes, the sea is never occupied, not even thermally; its justification is OPEN, and the sea-hole diagnostic shows where it fails;
- PRESCRIBED BACKGROUND: the history $a_4 = AHx_4$ with $A = 1$; the gas is a test field on it and cannot be its source (it violates the conditions C1, C2, C3 of `Revision/field_equations_a4/reports/ks-source-conditions.json`);
- the functional: Hartree plus the exact local exchange of the uniform gas, no correlation; the instantaneous (adiabatic) states, supported but not proved by $Q_{max} \ll 1$.

HYPOTHESIS: none.

OPEN: the time-dependent (non-adiabatic) evolution of the gas; a thermal treatment of the sea; the justification of the filling convention; the limit $L \to \infty$ wherever the record does not establish it ($N = 688$ at $a_{4,0} = 0$, the 7 interacting states of Section 15.2 whose limit is not established, whether self-consistent states exist where the iteration fails, and every state not computed at $L \neq 3$); what drives the history, since this gas cannot (Chapter 22 lists these problems). Nothing in this chapter concerns the creation of universes, pairs of universes or the matter-antimatter asymmetry.

15.32 Exercises

Exercise 1 (closed shells). (a) Show that $r_3(3) = 8$ and $r_3(5) = 24$. (b) Starting with the eight zero modes and filling the brane band shell by shell, compute the closed shells up to $n_2 = 5$. (c) Which of them is nearest to 688/4, and why is it the record's N_{mid}?

Answer. (a) $n_1^2 + n_2^2 + n_3^2 = 3$ only with three squares equal to 1, so $(\pm 1, \pm 1, \pm 1)$: $2^3 = 8$ vectors. For 5 the squares must be $4 + 1 + 0$: the number 2 can stand in any of the 3 places, the number 1 in any of the 2 remaining places, and each has two signs, so $3 \cdot 2 \cdot 2 \cdot 2 = 24$ vectors. (b) With $g = 4r_3(n_2)$ and $r_3(1), \ldots, r_3(5) = 6, 12, 8, 6, 24$: $8 + 24 = 32$; $32 + 48 = 80$; $80 + 32 = 112$; $112 + 24 = 136$; $136 + 96 = 232$. Rule: add $4r_3(n_2)$ for each new shell. (c) $688/4 = 172$; the distances are $|136 - 172| = 36$ and $|232 - 172| = 60$, so 136 is nearest, the rule of `Revision/kohn_sham/results/parameters.json` (particleNumbers.rule).

Exercise 2 (why the gap shrinks more slowly than $e^{-a_{4,0}}$). Let $s(k) = \varepsilon_{band}(k)/k$ and assume that s decreases as k grows. (a) Use the rescaling identity to show that $\Delta_{KS}(a_{4,0})/\Delta_{KS}(0) > e^{-a_{4,0}}$ for $N = 8$ and $a_{4,0} > 0$. (b) Compute s at the momenta $0.25\,e^{-a_{4,0}}$, $a_{4,0} = 0, 1, 2$, from the gaps 0.4307337, 0.1703493, 0.0641594 (Notebook 15a, Out [7]), and compare with $c = 1.9051482536$.

Answer. (a) Section 15.4: $\Delta_{KS}(a_{4,0}) = \varepsilon_{band}(k_a)$ with $k_a = 0.25\,e^{-a_{4,0}}$, so

$$\frac{\Delta_{KS}(a_{4,0})}{\Delta_{KS}(0)} = \frac{k_a\, s(k_a)}{0.25\, s(0.25)} = e^{-a_{4,0}}\,\frac{s(k_a)}{s(0.25)} > e^{-a_{4,0}}.$$

Rule: write each band level as $k\,s(k)$; $k_a/0.25 = e^{-a_{4,0}}$; and $s(k_a) > s(0.25)$ because $k_a < 0.25$ and s decreases. (b) $s(0.25) = 0.4307337/0.25 = 1.722935$; $s(0.0919699) = 0.1703493/0.0919699 = 1.852229$; $s(0.0338338) = 0.0641594/0.0338338 = 1.896310$. Rule: divide each gap by its momentum ($0.25\,e^{-1} = 0.0919699$, $0.25\,e^{-2} = 0.0338338$). The values grow as k shrinks and approach $c = 1.905148$, the slope at $k = 0$: the assumption holds on these points, and the ratios $1.852229/1.722935 = 1.0750$ and $1.896310/1.722935 = 1.1006$ are exactly the factors by which the measured ratios 0.39549 and 0.14895 exceed $e^{-1} = 0.36788$ and $e^{-2} = 0.13534$.

Exercise 3 (counting levels with the phase). For the free block $j = +1$ at $k = 0$ use the exact levels of Section 15.3 ($M = 1$, $L = 3$): the even levels $\sqrt{1 + (n\pi/3)^2}$ and the odd levels 1.2922928, 2.0106286 (Notebook 15e, Out [6]). (a) How many levels lie strictly between $\varepsilon = 0$ and $\varepsilon = 2$? (b) Between which two multiples of $\pi/2$ does $\Phi(2)$ lie? (c) Why is $\Phi(0) = 0$ exactly?

Answer. (a) Even: $n = 1$ gives $\sqrt{1 + 1.0966} = 1.4479719 < 2$, $n = 2$ gives $\sqrt{1 + 4.3865} = 2.3208815 > 2$. Odd: $1.2922928 < 2 < 2.0106286$. So two levels: the odd label 0 (target $\pi/2$) and the even label 1 (target π). (b) Φ increases strictly, has passed the targets $\pi/2$ (at 1.2923) and π (at 1.4480), but not yet $3\pi/2$ (the odd label 1, at 2.0106); so $\pi < \Phi(2) < 3\pi/2$, that is $1 < \Phi(2)/\pi < 1.5$, as Figure 15e.1 shows. (c) At $\varepsilon = 0$, $k = 0$, $v = 0$ the angle equation is $\theta' = -M \sin 2\theta$ with $\theta(-L) = 0$; the constant $\theta = 0$ solves it, and a solution of such an equation is fixed by its start value, so $\theta(0) = 0$. (This is the zero mode, $b = 0$; Notebook 15e checks that the computed value is exactly 0.0, Out [3].)

Exercise 4 (Anderson weights for two residuals). (a) For $p = 2$ solve the bordered system of Section 15.5 and show $c_1 = (G_{22} - G_{12})/(G_{11} - 2G_{12} + G_{22})$, $c_2 = 1 - c_1$. (b) Evaluate it for the residuals $r_1 = (2, 1)$ and $r_2 = (1, -1)$, and compare $|c_1 r_1 + c_2 r_2|^2$ with $|r_1|^2$ and $|r_2|^2$.

Answer. (a) With $c_2 = 1 - c_1$, $F = |c_1 r_1 + (1 - c_1) r_2|^2 = c_1^2 G_{11} + 2c_1(1 - c_1) G_{12} + (1 - c_1)^2 G_{22}$. Rule: expand the square with the dot products $G_{ik} = r_i \cdot r_k$. Then $dF/dc_1 = 2c_1 G_{11} + 2(1 - 2c_1) G_{12} - 2(1 - c_1) G_{22} = 0$. Rule: differentiate each term. Collecting c_1: $c_1(G_{11} - 2G_{12} + G_{22}) = G_{22} - G_{12}$, which is the claim (the same as eliminating ν from the bordered system). (b) $G_{11} = 4 + 1 = 5$, $G_{22} = 1 + 1 = 2$, $G_{12} = 2 - 1 = 1$, so $c_1 = (2 - 1)/(5 - 2 + 2) = 0.2$ and $c_2 = 0.8$. The combined residual is $0.2\,(2, 1) + 0.8\,(1, -1) = (1.2, -0.6)$ with $|\cdot|^2 = 1.44 + 0.36 = 1.8$, smaller than $|r_2|^2 = 2$ and $|r_1|^2 = 5$; check: $F(c_1) = 5c_1^2 - 2c_1 + 2$ has its minimum 1.8 at $c_1 = 0.2$.

Exercise 5 (the grand potential). For fixed levels and without interaction show that, level by level, $\varepsilon f - T S_1 - \mu f = -T \ln(1 + e^{-x})$, where $S_1 = -[f \ln f + (1 - f) \ln(1 - f)]$ and $x = (\varepsilon - \mu)/T$; conclude $\Omega = E - TS - \mu N$.

Answer. Line by line. $1 - f = f(-x) = 1/(1 + e^{-x})$, so $\ln(1 - f) = -\ln(1 + e^{-x})$. Rule: the identity $1 - f(x) = f(-x)$ of Section 15.26. Next, $\ln f - \ln(1 - f) = \ln \frac{f}{1-f} = -x$. Rule: $\frac{1-f}{f} = e^{x}$. Hence $S_1 = -f[\ln f - \ln(1 - f)] - \ln(1 - f) = fx - \ln(1 - f)$. Rule: write $f \ln f +$

$(1-f)\ln(1-f) = f[\ln f - \ln(1-f)] + \ln(1-f)$. Then $TS_1 = (\varepsilon-\mu)f - T\ln(1-f)$, because $Tx = \varepsilon - \mu$, and $\varepsilon f - TS_1 - \mu f = T\ln(1-f) = -T\ln(1+e^{-x})$. Summing with the degeneracies: $E - TS - \mu N = -T\sum g\ln(1+e^{-x}) = \Omega$, with $E = \sum gf\varepsilon$ and $N = \sum gf$. With interaction both sides contain the same term $-2\,\mathrm{Vol}_7 \int e^{6Hy} e_{int}\, dy$ (Section 15.26); the solver checks the equality in all 135 states (check thermo_grand_potential_two_forms, worst relative difference 1.7×10^{-14}).

Exercise 6 (the energy along the history from its slope). Notebook 15b, Out [7], gives for $N = 136$ without interaction $E(0) = 80.28222$, $E(0.5) = 51.24519$ and the slopes $dE/da_4 = -71.439756$ at $a_{4,0} = 0$ and -46.470842 at $a_{4,0} = 0.5$. (a) Estimate $E(0.5)$ from $E(0)$ with Euler's rule (one step with the slope at the start) and with the trapezoid rule (the mean of the two slopes). (b) Explain the signs of the errors.

Answer. (a) Euler: $80.28222 + 0.5 \cdot (-71.439756) = 80.28222 - 35.71988 = 44.56234$, too low by 6.68. Trapezoid: $80.28222 + 0.5 \cdot \frac{1}{2}(-71.439756 - 46.470842) = 80.28222 - 29.47765 = 50.80457$, too low by 0.44. Rule: $E(a+h) \approx E(a) + h\,E'(a)$ (Euler) and $E(a+h) \approx E(a) + \frac{h}{2}[E'(a) + E'(a+h)]$ (trapezoid), Chapter 2. (b) The slope becomes less negative along the history (the curve of Figure 15b.4 is convex, it bends upward). Euler uses the steepest slope, that of the start, for the whole step and so overestimates the drop. The trapezoid rule averages the two end slopes; but the slope rises fast at first and then more slowly, so between the two ends it lies above the straight line that joins its end values, and the average of the two end slopes is more negative than the true average slope: the drop is again overestimated, by much less. Notebook 15b uses Simpson's rule on 17 slices instead and obtains $E(2) - E(0)$ to 8×10^{-7} relative (Out [8]).

Exercise 7 (adiabaticity). (a) From Notebook 15c, Out [5], compute Q and the transition probability for $N = 136$ at $a_{4,0} = 0$ (matrix element 0.358861, energy difference 2.052930) and at $a_{4,0} = 2$ (matrix element 0.089223, energy difference 1.524416). (b) Why is $Q = 0$ exactly for $N = 8$? (c) Use the two-level formula of Section 15.26 to estimate μ of $N = 8$ at $a_{4,0} = 0$ and $T = 0.02$; the record has 0.2043728 (`Revision/kohn_sham/results/thermo/thermodynamics.csv`, `N8_lam0_a00_T20`). Why is the agreement worse than at $T = 0.01$?

Answer. (a) $Q = 0.358861/2.052930^2 = 0.358861/4.214522 = 0.085149$, probability $Q^2 = 0.00725$; at $a_{4,0} = 2$: $Q = 0.089223/2.323844 = 0.038395$, probability 0.00147. Rule: $Q = AH|\langle n|\partial_a h|m\rangle|/(\varepsilon_n - \varepsilon_m)^2$ with $AH = 1$ (Section 15.21). Both are far below 1: the gas follows its instantaneous states within the sectors. (b) For $N = 8$ only the zero modes at $k = 0$ are occupied, so transitions could start only in the sectors with $k = 0$, where the free $\partial_a h = -j\kappa k\sigma_3$ vanishes. With interaction the occupied orbitals are still the $k = 0$ orbitals, which do not feel the slice at all (the slice enters only through κk), so the self-consistent potentials do not change with a_4 either, and $\partial_a h = 0$ on these sectors: every matrix element vanishes. (c) $\mu = 0.4307337/2 - 0.01\ln 3 = 0.2153668 - 0.0109861 = 0.2043807$, against the record's 0.2043728: a difference of 8×10^{-6}, against 1.5×10^{-9} at $T = 0.01$. Rule: the formula keeps only the first band shell and uses $f(x) \approx e^{-x}$; at the higher temperature the next band shells (at 0.588 and above) are less suppressed, and the neglected terms grow like $e^{-(\varepsilon-\mu)/T}$, so the estimate is less accurate.

16 Checking the solution independently: the reference solver and the cross-check

Chapter 15 solved the Kohn-Sham equations of the field dirac16complex in the author's primordial universe with one program, the Revision Rust solver, and read physics from its numbers: levels,

energies, densities, pressures, heat capacities, all along the history in which ordinary 3-space inflates and the three extra times x_5, x_6, x_7 deflate exponentially. This chapter asks the question that every such calculation must answer before its numbers may be called results: how do we know that they are right? The Revision record answers it with a second program that shares no code with the first and solves the same equations by a different method (the **reference solver**), and with a third program that compares the two, number by number, with a rule for the allowed difference that was written down before any comparison was made (the **cross-check**). Three complete notebooks, 16a, 16b and 16c, repeat the essential steps and reproduce the numbers of the record.

16.1 What this chapter does

Why checking is a chapter of its own. A number printed by a program is not yet a result. Between the equations and the printed number stand a grid that replaces the continuous hidden direction by finitely many points, numbers in the computer that carry only about sixteen significant digits, thousands of lines of code in which a single wrong sign could hide, and the choices of the model itself. The first three can be tested by solving the same equations a second time in a completely different way: if two independent programs agree to many digits, within errors that each of them has measured, it is very unlikely that both are wrong in the same way. The fourth, the model, cannot be tested this way, because both programs share it; Section 16.25 says precisely what that means. The cross-check of the record did not only confirm the Rust solver: its first run failed, and the failure exposed a rounding error in the computation of the chemical potential that no test of either program alone had seen. This chapter tells that story too (Sections 16.20 to 16.24).

What is done, in order.

- Why a second program is needed and what agreement between two programs can and cannot show (Section 16.2).
- The two solvers side by side: what each one computes and how (Section 16.3).
- How the error of a grid calculation is measured: the order of convergence and the ratio test (Section 16.4), Richardson extrapolation and the uncertainty of the reference solver (Section 16.5), the canonical and refined runs that measure the uncertainty of the Rust solver (Section 16.6).
- The tolerance rule of the cross-check, derived line by line, and what the full cross-check of the record found (Sections 16.7 and 16.8).
- Notebook 16a, which runs the reference solver on five states, runs the Rust solver twice for each of them, applies the tolerance rule to 5140 comparisons and reproduces the worst cases of the record (Sections 16.9 to 16.12).
- Inside the reference solver: the exact levels of the free problem, the staggered grid, the matrix, counting eigenvalues, the exact discrete zero mode and the slope of the brane band (Sections 16.13 to 16.15), with Notebook 16b, which rebuilds the method by hand (Sections 16.16 to 16.19).
- How the cross-check caught a rounding error in the chemical potential, why sixteen digits were not enough, and how the computation was repaired (Section 16.20), with Notebook 16c (Sections 16.21 to 16.24).

- What the cross-check does not test, the closing summary and the exercises (Sections 16.25 to 16.27).

The three notebooks.

- Notebook 16a (needs Rust; 51 checks, 7 figures): the reference solver on a subset of five states, the Rust solver with its canonical and its refined numerics, and the tolerance rule on 5140 comparisons.
- Notebook 16b (no Rust; 31 checks, 7 figures): the method of the reference solver by hand on the free problem: the exact levels, the staggered grid, the matrix, Sturm counts and bisection, the zero mode, Richardson extrapolation, the brane-band slope.
- Notebook 16c (no Rust; 26 checks, 6 figures): the chemical potential with 40 digits, the rounding staircase of the direct sum, the faulty value of the first cross-check reproduced, the repair, and the rounding bounds of 45 states.

Notebook 16a is placed first because it shows the whole check at work; 16b then opens the reference solver and 16c the chemical potential.

The status of every statement. Every statement of this chapter carries one of the labels of Chapter 0.

- PROVED: the formulas of the method, each derived line by line in this chapter: the ratio test, Richardson extrapolation and why its uncertainty over-estimates the error, the factor 16/15 of the Rust uncertainty, the tolerance rule as a consequence of the triangle inequality, the exact free levels (in the record: check bc_exact_k0_spectra of `Revision/kohn_sham/reports/ks-theory-python.json`), the staggered matrix and its symmetry, the pivots of the Sturm count, the exact discrete zero mode, the Hellmann-Feynman slope of the brane band (check brane_band_slope of the same report), the slope $dN/d\mu$ of the Mermin condition, Newton's method, the well-conditioned rewriting of the Mermin condition and the first-order rounding bounds. Two facts of linear algebra are quoted, not proved: Sylvester's law of inertia and the spectral theorem for symmetric matrices.
- COMPUTED: every number of the comparisons. The reference solver's own checks are in `Revision/kohn_sham/reports/ks-reference.json` (37 checks, all PASS), the cross-check in `Revision/kohn_sham/reports/ks-crosscheck.json` (31 checks, all PASS, 162691 comparisons) and its table `Revision/kohn_sham/reports/ks-crosscheck-table.csv`; the notebooks reproduce them, with the measured differences given with each number.
- ASSUMED: that the grid errors have the assumed form (even powers of the cell width for the reference, fourth order for the Rust solver). This is not proved for the self-consistent problem; it is tested by the ratio test on every level and by a fourth grid for one state (Sections 16.4 and 16.5). Also ASSUMED, as in Chapters 14 and 15: the good sector and the Z2 mirror brane at $y = 0$; CHOSEN: the regular tip at $y = -L$ with $L = 3$; CONVENTION, justification OPEN: which levels count as particles.
- PRESCRIBED BACKGROUND: the history $a_4 = AHx_4$ with $A = 1$ (the Kohn-Sham states violate the conditions that the a_4 field equations put on their source: `Revision/field_equations_a4/reports/ks-source-conditions.json`).

- OPEN: the time-dependent (non-adiabatic) problem. HYPOTHESIS: none is used in this chapter.

What this chapter does not touch. Nothing in this chapter concerns pairs of universes, their creation, or matter and antimatter. The cross-check compares two programs that solve the same Kohn-Sham equations; it says nothing about whether any universe is created, in pairs or otherwise. The pairing theorems and their exact scope are the subject of Chapters 18 to 21.

Notation and units. The author's coordinates are $x_0, \ldots, x_7$: x_1, x_2, x_3 are ordinary 3-space, which inflates with the scale factor $e^{a_4} \sin^{1/6} z$; x_4 is the time; x_5, x_6, x_7 are the three extra times, which deflate exponentially with the scale factor $e^{-a_4} \sin^{1/6} z$; x_0 is the hidden space direction, with $z = 6Hx_0$ between 0 and $\pi/2$. The hidden coordinate is $y = \ln(\sin z)/(6H)$; it runs from the **tip** $y = -L$ to the **brane** $y = 0$. A **slice** is one instant of the history, and $a_{4,0}$ is the value of a_4 there. In all numbers $H = 1$ and $m = 1$, so energies and temperatures are in units of m and lengths in units of $1/H$. A state of the record is named like N136_lamp2_a20: $N = 136$ quanta, the coupling $+\lambda_2$ (the tags lam0, lamp1, lamm1, lamp2, lamm2 stand for $\lambda = 0, +\lambda_1, -\lambda_1, +\lambda_2, -\lambda_2$), the slice $a_{4,0} = 2.0$ (the two digits are ten times the slice); a thermal state ends in T10, T20 or T50 for the temperatures $T = 0.01$, 0.02, 0.05.

16.2 Why a second program, and what agreement can show

Four kinds of error. Suppose a program prints a number x for a quantity whose exact value is X. The **error** of x is the difference $x - X$. It has four sources.

- The **discretisation error**: the program replaces the continuous interval $-L \le y \le 0$ by finitely many points, so it solves a nearby problem, not the exact one. This error shrinks when the points are made denser.
- The **rounding error**: the computer stores each number with about sixteen significant digits (Section 16.20 explains exactly how), so almost every operation makes a tiny error, and long sums can make larger ones.
- **Mistakes in the program**: a wrong sign, a wrong index, a forgotten term. They do not shrink when the grid is refined.
- **Errors of the model or of its inputs**: a wrong formula in the theory, a wrong boundary condition, a wrong constant. The program then solves the wrong equations correctly.

What a second program tests. The record's reference solver is a second program written for this purpose. It shares no code with the Rust solver; it is written in another language (Python instead of Rust); it uses a different numerical method (a matrix on a grid instead of step-by-step integration, Section 16.3); and its only physics input is the theory file `Revision/kohn_sham/ks-theory.jso n`, which the Rust solver reads as well. Discretisation errors of two different methods are different, rounding errors take different paths, and a mistake in one program is very unlikely to be repeated, with the same size, in the other. So if the two programs agree within their measured errors, then, with high confidence, neither has a discretisation, rounding or programming error larger than those errors. But an error of the fourth kind is shared: both programs read the same theory file and use the same boundary conditions, so they would agree even if the model were wrong. The cross-check

tests the numerics, not the physics model. It also compares the two programs at the same tip cutoff, $L = 3$ (CHOSEN): agreement tests how accurately both programs solve the equations with $L = 3$, not how the results change when L grows. That dependence is measured separately, in `Revision/kohn_sham/tip_convergence/`, where, for two of the recorded states, the reference solver agrees with the Rust solver at $L = 3$ and at $L = 4$ in all 28 comparisons (Section 16.25).

Uncertainty, tolerance, ratio. Neither program knows its own error exactly (otherwise it could subtract it). What each can do is measure an **uncertainty**: a number U that, for reasons given in Sections 16.5 and 16.6, should be at least as large as the size $|x - X|$ of its error. The **tolerance** is the largest difference between the two programs that the comparison allows; Section 16.7 derives it from the two uncertainties. The **ratio** of a comparison is the difference of the two programs divided by the tolerance; the comparison passes when the ratio is at most 1.

Why the tolerance must be fixed in advance. A tolerance that is chosen after looking at the differences can always be made large enough for everything to pass, and then the comparison tests nothing. The record therefore fixes the tolerance rule in the cross-check program before any comparison and never adjusts it to a result (`Revision/kohn_sham/checker/crosscheck_ks.py`, its header, and the README of `Revision/kohn_sham/checker`). The rule was tested by its first use: it failed in one state, the tolerance was not widened, and the cause was found and repaired (Section 16.20).

16.3 The two solvers

The equations both solve. Both programs solve the Kohn-Sham problem of Chapters 14 and 15. At a slice $a_{4,0}$ an orbital of block type $j = \pm 1$ with 3-momentum of length k is a pair of real functions $a(y)$, $b(y)$ that obey

$$a' = Ma - \big(\kappa k + j(\varepsilon - v)\big)\, b, \qquad b' = \big(j(\varepsilon - v) - \kappa k\big)\, a - Mb, \qquad \kappa = e^{-Hy - a_{4,0}},$$

where the prime is d/dy, ε is the level, $M(y) = m + \frac{15}{16}\lambda S(y)$ the effective mass and $v(y) = -\frac{1}{16}\lambda n(y)$ the potential (`Revision/kohn_sham/ks-theory.json`, `blockEquation.realForm` and `exchange.kohnShamPotentials`). The boundary conditions are the regular tip $b(-L) = 0$ (CHOSEN) and the ASSUMED Z2 brane: even orbitals have $b(0) = 0$, odd orbitals $a(0) = 0$. The densities n and S are sums over the occupied orbitals, so the potentials depend on the solution, and the problem is solved again and again until it reproduces itself (self-consistency). At a temperature $T > 0$ the occupations are Fermi-Dirac numbers $f = 1/(1 + e^{(\varepsilon-\mu)/T})$, and the chemical potential μ is fixed by $\sum g f = N$. The list of states, the **canonical matrix**, holds 75 ground states (three particle numbers, five couplings, five slices) and 135 thermal states (three particle numbers, three couplings, five slices, three temperatures).

The Rust solver (Chapter 15). For a trial energy it integrates the two equations from the tip to the brane with the Runge-Kutta rule RK4 in $G = 900$ steps, counts levels with the Pruefer angle, and finds each level by Newton's method inside a bracket to a tolerance of 10^{-13}; self-consistency is reached with Anderson mixing to a residual of 10^{-11} (`Revision/kohn_sham/results/parameters.json`, numerics).

The reference solver (`Revision/kohn_sham/reference/run_reference.py` with the module `ks_fd.py` in the same folder). It places the two functions of an orbital on a **staggered grid** of

G cells: a at the centres of the cells and b at their ends. The differential equations then become the eigenvalue problem of a symmetric **tridiagonal matrix** with $2G - 1$ rows (a matrix whose only nonzero entries are on the main diagonal and its two neighbours). It finds each eigenvalue by its number, by counting how many eigenvalues lie below a trial value (the **Sturm count**) and halving an interval (**bisection**), so that no level can be missed; it then sharpens each eigenvalue and computes its eigenvector. Every quantity is computed on three grids, $G = 300$, 600 and 1200, and the three results are combined by **Richardson extrapolation** (Section 16.5) into a value R with a measured uncertainty U. Self-consistency is reached with Anderson mixing to a residual of 10^{-12}. The reference re-derives from their stated rules even the inputs it could have copied: the particle numbers 136 and 688 and the couplings λ_1, λ_2 (for $N = 8$: 0.01946 and 0.05838; `Revision/kohn_sham/reports/ks-reference.json`, check `parameters_calibration`).

Side by side.

	Rust solver	**reference solver**

What the reference computes for each state. A ground-state **job** (one unit of work of the program) solves the state, its Delta-SCF excited state (one quantum moved from the highest occupied to the lowest empty group of levels), four neighbouring slices $a_{4,0} \pm 0.002$ and $a_{4,0} \pm 0.004$ at fixed occupations (for the derivative dE/da_4 and the adiabaticity measure of Chapter 15), and the list of the lowest particle-hole excitations, each on the three grids. A thermal job solves the state and four neighbouring temperatures $T(1 \pm 0.01)$, $T(1 \pm 0.02)$ (for the heat capacity). The program also solves an exact-exchange variant of the 60 states with $\lambda \neq 0$, the rescaling partners of the 60 states with $a_{4,0} > 0$, a demonstration of a level crossing, and one state on a fourth grid (Section 16.5). Its report `Revision/kohn_sham/reports/ks-reference.json` records 37 checks of the reference on itself, all PASS.

16.4 Order of convergence: the ratio test

The error of a grid calculation. Let a grid have cells of width h ($h = L/G$ for G cells), and let $x(h)$ be a number computed on it whose exact value is X. For the staggered grid of the reference the error has an expansion in even powers of h (Section 16.14 shows where the even powers come from):

$$x(h) = X + c\,h^2 + d\,h^4 + e\,h^6 + \ldots,$$

where the numbers c, d, e do not depend on h. Such a method is said to be of **second order** (or to have **order of convergence** 2), because for small h the first term $c\,h^2$ dominates: halving h divides the error by about $2^2 = 4$. The expansion is ASSUMED for the self-consistent problem; the ratio test below checks it on the computed numbers themselves.

The ratio test, line by line. Compute x on three grids with the cell widths h, $h/2$ and $h/4$ (for the reference $G = 300$, 600, 1200, that is $h = 0.01$, 0.005, 0.0025).

$$x(h) - x(h/2) = c\,h^2 - c\,\tfrac{h^2}{4} + d\,h^4 - d\,\tfrac{h^4}{16} + \cdots = \tfrac{3}{4}\,c\,h^2 + \tfrac{15}{16}\,d\,h^4 + \ldots$$

Rule: subtract the expansion with $h/2$ in place of h from the expansion with h; X cancels, and $(h/2)^2 = h^2/4$, $(h/2)^4 = h^4/16$.

$$x(h/2) - x(h/4) = \tfrac{3}{4}\,c\,\tfrac{h^2}{4} + \tfrac{15}{16}\,d\,\tfrac{h^4}{16} + \ldots$$

Rule: the same subtraction with $h/2$ in place of h, so every h^2 gets a factor $\frac{1}{4}$ and every h^4 a factor $\frac{1}{16}$.

$$\frac{x(h) - x(h/2)}{x(h/2) - x(h/4)} = \frac{\frac{3}{4}c\,h^2\,(1 + \frac{5}{4}\frac{d}{c}h^2 + \ldots)}{\frac{3}{16}c\,h^2\,(1 + \frac{5}{16}\frac{d}{c}h^2 + \ldots)} = 4\left(1 + \tfrac{15}{16}\,\tfrac{d}{c}\,h^2 + \ldots\right).$$

Rule: take $\frac{3}{4}ch^2$ and $\frac{3}{16}ch^2$ out of the two brackets ($\frac{15}{16}/\frac{3}{4} = \frac{5}{4}$ and $\frac{15}{256}/\frac{3}{16} = \frac{5}{16}$), then divide, using $1/(1+s) = 1 - s + \ldots$ for small s, so that $\frac{5}{4} - \frac{5}{16} = \frac{15}{16}$.

So the **convergence ratio** $(x(h) - x(h/2))/(x(h/2) - x(h/4))$ is 4 up to a correction of order h^2. A ratio close to 4 shows that the grids are fine enough for the h^2 term to dominate (the **asymptotic regime**), which is what Richardson extrapolation needs. The test uses only computed numbers, not the unknown X.

An example from the record. Notebook 16a prints the Kohn-Sham energy of the state N136_lamp2_a20 on the three grids: $E_{KS}(300) = 12.449082943357$, $E_{KS}(600) = 12.449020346521$, $E_{KS}(1200) = 12.449004697554$. The two differences are 6.2597×10^{-5} and 1.5649×10^{-5}, and their ratio is 4.00006: second order, in the asymptotic regime. The reference applies the test to every level of every ground state and requires the median ratio of each state to lie within 0.05 of 4; the worst state is within 7.4×10^{-5} of 4 (`Revision/kohn_sham/reports/ks-reference.json`, check `richardson_asymptotic_ratio`).

16.5 Richardson extrapolation and the uncertainty of the reference

The idea. If we know the form of the error, we can combine results on several grids so that the leading error terms cancel. This is **Richardson extrapolation**, named after the meteorologist Lewis Fry Richardson, who used it in 1911.

One step, line by line. Start from the expansion of Section 16.4 on the grids h and $h/2$.

$$x(h/2) = X + c\,\tfrac{h^2}{4} + d\,\tfrac{h^4}{16} + \ldots$$

Rule: put $h/2$ in place of h in the expansion.

$$4\,x(h/2) - x(h) = 3X + (1-1)\,c\,h^2 + (\tfrac{4}{16} - 1)\,d\,h^4 + \cdots = 3X - \tfrac{3}{4}\,d\,h^4 + \ldots$$

Rule: multiply the line above by 4 and subtract the expansion for h; the $c\,h^2$ terms cancel because $4 \cdot \frac{1}{4} = 1$.

$$r(h) = \frac{4\,x(h/2) - x(h)}{3} = X - \tfrac{1}{4}\,d\,h^4 + \ldots$$

Rule: divide by 3. The **one-step value** $r(h)$ has no h^2 error left; its error starts with h^4.

The second step, line by line. The same step on the finer pair $h/2$, $h/4$ gives

$$r(h/2) = \frac{4\,x(h/4) - x(h/2)}{3} = X - \tfrac{1}{4}\,d\,\tfrac{h^4}{16} + \cdots = X - \tfrac{1}{64}\,d\,h^4 + \ldots$$

Rule: the line before, with $h/2$ in place of h, so h^4 becomes $h^4/16$.

$$16\,r(h/2) - r(h) = 15X + (\,-\tfrac{16}{64} + \tfrac{1}{4})\,d\,h^4 + \cdots = 15X + \ldots$$

Rule: multiply by 16 and subtract $r(h)$; the h^4 terms cancel because $16 \cdot \frac{1}{64} = \frac{1}{4}$. What remains are terms of order h^6.

$$R = \frac{16\,r(h/2) - r(h)}{15} = X + O(h^6).$$

Rule: divide by 15. The notation $O(h^6)$ means terms that are at most a constant times h^6.

The same value in one line. Insert the two one-step values:

$$16\,r(h/2) - r(h) = \frac{64\,x(h/4) - 16\,x(h/2)}{3} - \frac{4\,x(h/2) - x(h)}{3} = \frac{64\,x(h/4) - 20\,x(h/2) + x(h)}{3}.$$

Rule: $16 \cdot \frac{4x(h/4) - x(h/2)}{3}$ multiplied out, then the two fractions with the same denominator subtracted, collecting $-16 - 4 = -20$ for $x(h/2)$.

$$R = \frac{64\,x(h/4) - 20\,x(h/2) + x(h)}{45}.$$

Rule: divide by 15, and $3 \cdot 15 = 45$. The three weights add up to $(64 - 20 + 1)/45 = 1$, as they must: if all three grids gave the same number, R would be that number.

The uncertainty. The reference states as the uncertainty of R

$$U = \bigl|R - r(h/2)\bigr| + 2 \cdot 10^{-12}\max(1, |R|).$$

Why this is a safe estimate, line by line:

$$R - r(h/2) = \Big(X + O(h^6)\Big) - \Big(X - \tfrac{1}{64} d\, h^4 + O(h^6)\Big) = \tfrac{1}{64}\, d\, h^4 + O(h^6).$$

Rule: subtract the two expansions derived above; X cancels.

So the first term of U is the size of the h^4 error of the finest one-step value $r(h/2)$, while R itself has only an h^6 error. When h is small, h^6 is much smaller than h^4, so U is larger than the error of R: it over-estimates it. The second term, $2 \cdot 10^{-12}$ times the size of R (at least 1), is a **floor** for the rounding errors of the computer, which do not shrink with h.

An example. For N136_lamp2_a20 the one-step values are $r(h) = 12.448999480909$ and $r(h/2) = 12.448999481232$, the three-grid value is $R = 12.448999481253$, and $U = 4.6 \times 10^{-11}$ (Notebook 16a, In [6]; the record has $R = 12.44899948125322$ with $U = 4.6 \times 10^{-11}$, `Revision/kohn_sham/reference/README.md`). The single grid $G = 1200$ is 5.2×10^{-6} away from R; two Richardson steps have gained five significant digits.

Testing the uncertainty on a fourth grid. The argument above rests on the ASSUMED form of the error. The record tests it. One state, N136_lamp2_a20 (the strongest coupling, with the largest densities at the tip), is solved on a fourth grid as well, $G = 2400$. From $(300, 600, 1200)$ the three-grid value R_{123} with its uncertainty U_{123} is formed, and from $(600, 1200, 2400)$ the three-grid value R_{234}. The error of R_{234} is of order $(h/2)^6 = h^6/64$, so it is about 64 times smaller than the error of R_{123}; hence $|R_{123} - R_{234}|$ is practically the error of R_{123}, and the test is whether it is at most U_{123}. For all 19 classes of quantities (energies, levels, integrals, values at the tip and at the brane, five profiles with 151 points each) it is: the largest ratio $|R_{123} - R_{234}|/U_{123}$ is 0.787, for the value of the pressure p_0 at the tip (`Revision/kohn_sham/reports/ks-reference.json`, check `richardson_uncertainty_validated`). Notebook 16a repeats this test (In [7], Figure 16a.2). The uncertainty is therefore an honest estimate, and it is not hugely larger than the error either, which a useful estimate must also be.

16.6 The uncertainty of the Rust solver: canonical and refined runs

The idea. The Rust solver uses the Runge-Kutta rule RK4, whose error over the whole interval is proportional to h^4 for the step width $h = L/G$ (Chapter 2). If the step is halved, the error is divided by $2^4 = 16$. The record therefore runs every state twice: with the **canonical numerics** of the committed results and with the **refined numerics**, which halve the step and tighten the other tolerances. The canonical numerics are $G = 900$ steps, a root tolerance of 10^{-13} and a self-consistency tolerance of 10^{-11}; the refined numerics are $G = 1800$, 10^{-14} and 10^{-12} (`Revision/kohn_sham/checker/measure_rust_refinement.py`, which writes `Revision/kohn_sham/checker/rust-refinement.json`).

The factor 16/15, line by line. Let e be the error of the canonical result x_c, so $x_c = X + e$, and let the refined result be x_r.

$$x_r = X + \tfrac{e}{16}.$$

Rule: halving the step of a fourth-order method divides the error by $2^4 = 16$ (ASSUMED error model; the other tolerances are tightened so that they do not spoil it).

$$x_c - x_r = e - \tfrac{e}{16} = \tfrac{15}{16}\, e.$$

Rule: subtract the two lines; X cancels.

$$e = \tfrac{16}{15}\,(x_c - x_r), \qquad U_{Rust} = \tfrac{16}{15}\,|x_c - x_r|.$$

Rule: multiply by $\frac{16}{15}$; the size of the canonical error is the **Rust uncertainty**.

So the difference between the two runs, which can be measured, gives the error of the canonical run, which cannot. For example, Notebook 16a (In [13]) measures $|x_c - x_r| = 7.529 \times 10^{-10}$ for the Kohn-Sham energy of N688_lam0_a00, so $U_{Rust} = \frac{16}{15} \cdot 7.529 \times 10^{-10} = 8.03 \times 10^{-10}$.

Two conditions. First, the measured difference applies to the committed results only if the canonical run made for the measurement reproduces them. The record checks this for every state: the canonical runs reproduce the committed matrix with every difference zero (`Revision/kohn_sham/reports/ks-crosscheck.json`, check `rust_refinement_applies_to_matrix`). Second, some quantities (the Delta-SCF energy, the adiabaticity measure, the finite-difference dE/da_4, the heat capacity) are not printed by the single runs of the measurement. For them the cross-check uses the largest canonical-minus-refined difference over the whole canonical matrix, taken from the Rust solver's determinism report; the values are listed in `Revision/kohn_sham/reports/ks-crosscheck.json` under `rust_matrix_wide_uncertainties` (for example 2.135×10^{-9} for the levels and 5.689×10^{-9}, relative, for the heat capacity).

16.7 The tolerance rule, fixed in advance

The rule. For every number that both programs compute, the cross-check requires

$$|x_{Rust} - x_{ref}| \le 3\,(U_{ref} + U_{Rust}) + 10^{-12} \cdot s,$$

where U_{ref} is the Richardson uncertainty of the reference, U_{Rust} the measured uncertainty of the Rust solver, and the **scale** s is $\max(1, |x_{ref}|)$ for a single number and the largest value of the profile for a point of a profile. The right side is the **tolerance**, and the left side divided by the right side is the **ratio**.

Why the two uncertainties are added, line by line. Let X be the exact value.

$$x_{Rust} - x_{ref} = (x_{Rust} - X) - (x_{ref} - X).$$

Rule: add and subtract X.

$$|x_{Rust} - x_{ref}| \le |x_{Rust} - X| + |x_{ref} - X|.$$

Rule: the **triangle inequality** $|p - q| \le |p| + |q|$ for any two numbers p, q.

$$|x_{Rust} - x_{ref}| \le U_{Rust} + U_{ref}.$$

Rule: each uncertainty is at least the size of its program's error (that is what an uncertainty is meant to be).

So if both uncertainties are honest, the difference can never exceed their sum. The rule allows three times the sum, because the uncertainties are estimates, not proven bounds (Sections 16.5 and 16.6 explain the assumptions behind them): the factor 3 keeps a comparison from failing merely because an estimate was a little too small, while a real mistake, which usually produces differences many times the uncertainties, still fails. The last term, 10^{-12} times the scale, is a floor for rounding, which neither uncertainty measures.

Propagated uncertainties, line by line. Some compared quantities are built from others, and their uncertainties are added up the same way. The free energy is $F = E - TS$, so

$$F_{Rust} - F = (E_{Rust} - E) - T\,(S_{Rust} - S), \qquad U_F = U_E + T\,U_S.$$

Rule: subtract the exact $F = E - TS$ from the computed one, then apply the triangle inequality as above. In the same way the grand potential $\Omega = F - \mu N$ gets $U_\Omega = U_F + N\,U_\mu$. The derivative of the energy along the history has the energy-momentum form $dE/da_4 = -6\,\mathrm{Vol}_7 \int e^{6Hy}(p_3 - p_t)\,dy = -3\,(I_3 - I_t)$, where I_3 and I_t are the integrals $2\,\mathrm{Vol}_7 \int e^{6Hy} p_3\,dy$ and $2\,\mathrm{Vol}_7 \int e^{6Hy} p_t\,dy$ that the solvers report; hence its uncertainty is $3\,(U_{I_3} + U_{I_t})$. The exchange difference $\Delta E_x = \frac{\lambda}{32}\,2\,\mathrm{Vol}_7 \int e^{6Hy} Q^2\,dy$ is quadratic in the profile Q, and a relative change δ of Q changes Q^2 by the relative amount $(1+\delta)^2 - 1 = 2\delta + \delta^2 \approx 2\delta$; hence its uncertainty is twice the relative uncertainty of Q times $|\Delta E_x|$.

A floor for difference quotients. The heat capacity is also computed as dE/dT, a **difference quotient**: energies at the temperatures $T \pm dT$ (and $T \pm 2dT$) are subtracted and divided by multiples of $dT = 0.01\,T$. Each energy is a sum over N occupied states of levels that are computed only to a tolerance (the Rust solver finds each level to its root tolerance 10^{-13}; the reference stops its self-consistency at 10^{-12}), so each energy carries a small noise of up to about N times that tolerance, and dividing by dT magnifies the noise to about $N \times \text{tolerance}/dT$. The cross-check adds this floor for each solver: $N \cdot 10^{-13}/dT$ for the Rust solver and $N \cdot 10^{-12}/dT$ for the reference (in its own report each solver uses the same floor for its identity $C_V = dE/dT$). For $N = 8$ and $T = 0.05$, where $dT = 5 \times 10^{-4}$, the two floors are 1.6×10^{-9} and 1.6×10^{-8}.

A worked comparison. Notebook 16a (In [14]) shows every piece of one comparison, the Kohn-Sham energy of N8_lamm2_a00. Rust gives 0.002862652173608389 and the reference 0.002862652173734779, a difference of 1.264×10^{-13}. The uncertainties are $U_{ref} = 2.096 \times 10^{-12}$ and $U_{Rust} = 1.214 \times 10^{-13}$. The tolerance is

$$3\,(2.096 + 0.1214) \times 10^{-12} + 10^{-12} \cdot 1 = 6.652 \times 10^{-12} + 1.000 \times 10^{-12} = 7.652 \times 10^{-12},$$

Rule: insert the numbers; the scale is $\max(1, 0.00286) = 1$. The ratio is $1.264 \times 10^{-13} / 7.652 \times 10^{-12} = 0.0165$: the two programs agree to less than a sixtieth of what the rule allows. (The notebook works with the unrounded uncertainties, $U_{ref} = 2.0955 \times 10^{-12}$ and $U_{Rust} = 1.2145 \times 10^{-13}$, and therefore prints the tolerance 7.651×10^{-12}; the last digit differs only because the four-digit inputs above are rounded. The ratio is 0.0165 either way.)

16.8 What the full cross-check found

The cross-check program `Revision/kohn_sham/checker/crosscheck_ks.py` compares the full canonical matrix. Its report `Revision/kohn_sham/reports/ks-crosscheck.json` holds 31 checks, all PASS, with 162691 comparisons in all (run of 2026-10-08). Twenty of the checks are classes of comparisons; for each, the table gives the number of comparisons and the largest ratio found (from the details of the checks in that report).

check	what is compared	comparisons	largest ratio
`ground_occupations_and_groups`	occupied levels, occupations, HOMO and LUMO groups	300	identical
`ground_energies`	E_{KS}, E_{band}, E_{int}	225	0.148
`ground_homo_lumo_gap`	HOMO, LUMO, Kohn-Sham gap	225	0.001
`ground_eigenvalues`	every level present in both label sets	9616	0.324
`excited_delta_scf`	Delta-SCF energy, excited energy	150	0.296
`excited_particle_hole_lists`	particle-hole excitations	4842	0.001
`emt_integrals`	the five energy-momentum integrals	375	0.225
`emt_brane_tip_values`	ρ, p_3, p_t, p_0 at the brane and the tip	600	0.495
`ground_profiles`	ten profiles at 151 points	113250	0.495
`exchange_delta_E_x`	the exchange difference ΔE_x	75	0.044
`adiabatic_dE_da4`	dE/da_4 in two forms	150	0.122
`adiabatic_Q_max`	the adiabaticity measure and its pair	225	0.314
`exx_variant_scf`	the exact-exchange variant	240	0.128
`rescaling_partners`	the rescaling partners	180	0.137
`crossing_demonstration`	the level-crossing demonstration	31	0.111
`thermo_state_functions`	μ, E, S, F, Ω in two forms	810	0.284
`thermo_derivatives`	C_V, dE/dT, $-dF/dT$	405	0.226
`thermo_sea_hole_diagnostic`	the sea-hole diagnostic of the filling convention	270	0.048
`thermo_levels`	every level of every thermal state, label by label	34378	0.312
`thermo_mu_high_precision`	μ recomputed with 40 digits, and Ω with it	270	0.050

How the comparisons are counted. The column adds up to 166617, more than the 162691 comparisons of the report, because the two numbers count slightly different things. The report counts the 5447 rows of the comparison table `ks-crosscheck-table.csv` (one row for each compared single quantity, such as an energy, an integral or a chemical potential, with both values, both uncertainties, the tolerance and the ratio) plus the 9616 level, 113250 profile and 34378 thermal-level comparisons, which are summarised in the report instead of being written as rows: $5447 + 9616 + 113250 + 34378 = 162691$. The column counts, for each class, every test the class makes. This gives two differences. (i) The other 17 classes of the table also make 3934 yes/no tests that write no row of the comparison table: whether the two programs occupy the same levels, find the same HOMO and LUMO groups, assign the same particle-hole excitations with the same multiplicities, and similar flags. (ii) 8 of the 5447 rows belong to two checks that are not in the table: the bulk edge (`parameters_particle_numbers`) and seven coupling strengths (`parameters_couplings`). So the column is $162691 - 8 + 3934 = 166617$.

The other eleven checks are preconditions, consistency tests and diagnostics: the three input reports pass every check (`inputs_all_pass`: at the time of the cross-check the reference report had 37 of 37, the Rust solver report 42 of 42 and the Rust determinism report 14 of 14); the canonical single runs reproduce the committed matrix (`rust_refinement_applies_to_matrix`, and its exact-exchange variant); both solvers solve the same problem and read the same theory file (`problem_definition_identical`); the reference re-derives the same particle numbers and couplings (`parameters_particle_numbers`, `parameters_couplings`); the floating-point chemical potentials lie within their rounding bounds (`thermo_mu_rounding_diagnostic`, Section 16.20); the Rust solver keeps the rounding bound of μ that it states itself (`thermo_mu_rust_stated_bound`, explained below); and the reference's own output is reproducible: the cross-check runs the reference a second time into a fresh folder and finds all 340 result files and the report byte for byte identical (`reference_outputs_lf_only`, `reference_manifest`, `reference_repeat_byte_identical`).

The two newest checks. The cross-check was run again on 2026-10-08 against the current Rust solver, and two checks were added (`Revision/kohn_sham/checker/README.md`, History 3); the 29 former checks gave the same results as before.

- `thermo_levels` compares every level of every thermal state, label by label, exactly as `ground_eigenvalues` does for the ground states: 33973 levels in the 135 thermal states, with the same tolerance rule and with $U_{Rust} = \frac{16}{15}$ times the largest canonical-minus-refined difference over the levels of the state. It also makes three yes/no tests in each of the 135 states: every level with an occupation $f \geq 10^{-12}$ in one program's set is present in the other's; the Rust labels of each sector start where the Rust ground-state files say they start; and the reference's ranks of each sector start at 0. These $3 \cdot 135 = 405$ tests bring the count to $33973 + 405 = 34378$. The largest ratio is 0.312 (N688_lamm1_a00_T50, level 0:+1:odd:2: Rust 2.90931115629902, reference 2.90931115615719, difference 1.418×10^{-10}, tolerance 4.548×10^{-10}).

- `thermo_mu_rust_stated_bound` is not a comparison of the two programs but a test of a promise. For every thermal state the Rust solver writes, next to μ, a bound on the rounding error of its own root, the column `mu_rounding_bound` of `Revision/kohn_sham/results/thermo/thermodynamics.csv` (the bound B_{well} of Section 16.20). The check recomputes the root of $\sum gf = N$ with 40 digits on the Rust levels and requires $|\mu_{Rust} - \text{root}| \leq$ `mu_rounding_bound` in all 135 states (two yes/no tests per state, 270 in all). It must use the exact doubles of the Rust run, not the printed 16-digit numbers, because rounding the printed numbers to 16 digits alone changes μ by up to about 6×10^{-16}, as much as the bound itself.

The largest ratio $|\mu_{Rust} - \text{root}|/\text{bound}$ is 0.149 (N688_lam0_a00_T10: 1.028×10^{-16} against 6.909×10^{-16}); for N8_lamm1_a00_T10, the state of Section 16.20, it is 2.519×10^{-17} against 3.154×10^{-16}.

Notebook 16a (In [2]) reads both checks from the report and prints their sizes.

What the table shows. No comparison of the whole matrix uses even half of its tolerance: the largest ratio is 0.495, for the energy density ρ at the tip of N8_lamm2_a00, where the densities are largest and both programs are least accurate. Many ratios are far smaller. Every one of these comparisons is made at the same tip cutoff $L = 3$; the dependence on L is measured separately (Section 16.25). Status: COMPUTED; the record files are named above, and Notebook 16a reproduces the worst case of six of the classes.

16.9 Example: the reference solver on a subset and the cross-check (Notebook 16a)

Notebook 16a repeats the cross-check for a **subset** of five states: three ground states and two thermal states, four of them chosen because the full cross-check found its largest ratios there, and the fifth (N688_lam0_a00) because it has the most quanta. It runs the reference program of the repository on these states and on the fourth grid, checks that every new number reproduces the committed reference files, shows the convergence and Richardson extrapolation at work, builds and runs the Rust solver with its canonical and its refined numerics, applies the tolerance rule (Section 16.7) to 5140 comparisons, and reproduces 97 rows of the committed comparison table and the worst cases of six classes of the full cross-check. It needs Rust, takes two to six minutes on a fast computer (more when other programs keep it busy) and about ten minutes on a typical laptop, draws seven figures and ends with the line ALL 51 CHECKS PASSED (notebook 16a).

16.10 How to run Notebook 16a

Step 1. What this notebook does and what it needs.

Notebook 16a (Running the reference solver on a subset and the cross-check) is the file `Revision/textbook/notebooks/16a_reference_crosscheck.ipynb` of the repository Dirac_claude. It runs the independent Python reference solver of the repository on five Kohn-Sham states of dirac16complex in the deflating primordial field (three ground states and two thermal states, four of them chosen because the full cross-check found its largest differences there) and on a fourth, finer grid for one state, checks that every new result reproduces the committed reference record, shows how the grids converge and how Richardson extrapolation removes the grid error, builds the Rust solver and runs it with its canonical and its refined numerics to measure its uncertainty, applies the tolerance rule of the cross-check to 5140 comparisons, and reproduces the corresponding rows and worst cases of the committed cross-check report. The raw outputs of the Rust program go into a temporary folder of the operating system (outside the repository), which the notebook deletes as soon as it has read them. It needs a computer with Windows 11, macOS or Linux, an internet connection for the installation, the program Git, and Python 3.12 or newer (the notebooks were built with Python 3.14.5) with these packages at exactly these versions: numpy 2.4.6, sympy 1.14.0, mpmath 1.3.0, matplotlib 3.11.0, jupyterlab 4.4.10, nbformat 5.10.4, nbclient 0.10.2, ipykernel 7.1.0 and nbconvert 7.16.6. The notebook itself imports numpy and matplotlib; the other packages run Jupyter, the

program that shows and runs notebooks. It also needs Rust (the program cargo, version 1.91.1 or newer), because it runs the Rust program revision_ks_solver, which is part of the repository and is built on your computer.

Step 2. Install Git and Python (once per computer).

A terminal is the window in which you type commands: on Windows the app Windows PowerShell (or Terminal), on macOS the app Terminal (it runs the shell zsh), on Linux any terminal (it runs the shell bash). Type every command of this section into a terminal exactly as printed, one line at a time, and press Enter after each line.

Windows: download Git from https://git-scm.com/download/win and install it with the default choices. Download Python from https://www.python.org/downloads/ and run the installer; in its first window tick the box "Add python.exe to PATH" before you click "Install Now".

macOS: download Python from https://www.python.org/downloads/ and run the installer. Then open the app Terminal and run this command, which installs Git and the compiler tools:

macOS (zsh):

```
xcode-select --install
```

Linux (Debian or Ubuntu; other distributions have packages of the same names): run these two commands:

Linux (bash):

```
sudo apt update
sudo apt install git python3 python3-venv
```

Then close the terminal and open a NEW one (a terminal opened before the installation does not know the new programs), and check the version of Python; it must print 3.12 or a higher number:

Windows (PowerShell):

```
py -3 --version
```

macOS (zsh) and Linux (bash):

```
python3 --version
```

If an older Linux prints a lower number (Ubuntu 22.04 has Python 3.10), install Python 3.12 with the following three commands, and in Step 3 type `python3.12` instead of `python3` in the command that creates the environment:

Linux (bash), only when the version is too low:

```
sudo add-apt-repository ppa:deadsnakes/ppa
sudo apt update
sudo apt install python3.12 python3.12-venv
```

Step 3. Get the repository and install the packages (once per computer).

The commands below download the repository (a few hundred megabytes; the folder then needs up to about 1 GB of disk space) into the folder Dirac_claude inside your home folder, create a private Python environment in the folder dirac-book-env inside your home folder (a private environment is a folder with its own copy of Python and of the packages, so that nothing else on your computer is changed), activate it (from then on the commands `python` and `jupyter` typed in this terminal are those of the environment, and the prompt starts with (dirac-book-env)), and install the packages at the pinned versions (this downloads about 90 MB and takes a few minutes; the environment takes about 400 MB of disk space). If you have done this step before, for this or for another notebook, skip it and go to Step 4; to get the newest version of the repository, run `git pull` in the repository folder after Step 4.

Windows (PowerShell):

```
cd $HOME
git clone https://github.com/once-ere/Dirac_claude.git
py -3 -m venv "$HOME\dirac-book-env"
Set-ExecutionPolicy -ExecutionPolicy RemoteSigned -Scope Process -Force
& "$HOME\dirac-book-env\Scripts\Activate.ps1"
python -m pip install --upgrade pip
python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
```

The line with `Set-ExecutionPolicy` allows PowerShell to run the activation script in this one window only; it changes nothing permanently.

macOS (zsh):

```
cd ~
git clone https://github.com/once-ere/Dirac_claude.git
python3 -m venv ~/dirac-book-env
source ~/dirac-book-env/bin/activate
python -m pip install --upgrade pip
python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
```

Linux (bash):

```
cd ~
git clone https://github.com/once-ere/Dirac_claude.git
python3 -m venv ~/dirac-book-env
source ~/dirac-book-env/bin/activate
python -m pip install --upgrade pip
python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
```

Step 4. In every new terminal: activate the environment and go into the repository folder.

Every later step starts in the repository folder with the environment active. Run these lines whenever you open a new terminal (they do no harm if the environment is already active):

Windows (PowerShell):

```
Set-ExecutionPolicy -ExecutionPolicy RemoteSigned -Scope Process -Force
& "$HOME\dirac-book-env\Scripts\Activate.ps1"
cd "$HOME\Dirac_claude"
```

macOS (zsh) and Linux (bash):

```
source ~/dirac-book-env/bin/activate
cd ~/Dirac_claude
```

Step 5. Install Rust and build the Rust program (Rust once per computer, the build once per program).

Windows: download `rustup-init.exe` from https://rustup.rs, run it and accept the default choices; if it reports that the Visual Studio C++ Build Tools are missing, let it install them (or install the workload "Desktop development with C++" from https://visualstudio.microsoft.com/visual-cpp-build-tools/ and run `rustup-init.exe` again). macOS and Linux: run the command below and accept the default choice (on Linux first run `sudo apt install build-essential`, which provides the linker that Rust needs).

macOS (zsh) and Linux (bash):

```
curl --proto "=https" --tlsv1.2 -sSf https://sh.rustup.rs | sh
```

Then close the terminal, open a new one, do Step 4 again, and check the version of cargo; it must print 1.91.1 or a newer version:

Windows, macOS and Linux:

```
cargo --version
```

Build the program with the following command, in the repository folder (the same command on all three systems):

Windows, macOS and Linux:

```
cargo build --release --manifest-path Revision/kohn_sham/solver/Cargo.toml
```

The first build takes about 1 minute; later builds reuse the result and take a few seconds. The program is then the file `Revision/kohn_sham/solver/target/release/revision_ks_solver` (on Windows with the ending `.exe`). The notebook runs the same build command itself before it uses

the program (it takes a second when the program is up to date), so the notebook also works if you skip this build; building here first shows any problem with Rust before the notebook starts.

Step 6. Run the notebook in JupyterLab.

In the repository folder, with the environment active, run these two lines (the first one goes into the folder of the notebooks):

Windows, macOS and Linux:

```
cd Revision/textbook/notebooks
jupyter lab 16a_reference_crosscheck.ipynb
```

JupyterLab opens in your web browser and shows the notebook (if no browser window opens, copy the address that starts with `http://localhost:8888/lab` from the terminal into the address bar of your browser). The name at the top right of the notebook must read Python 3 (ipykernel). Choose the menu Run > Run All Cells. While a cell runs, the label to its left shows `[*]`; when it has finished, the label shows a number. The notebook has finished when the last code cell shows a number; this takes about 10 minutes on a typical laptop. Scroll to the end and compare the last printed lines with the lines in the step "What the notebook writes and what you must see" below. To keep the results, save the notebook (menu File > Save Notebook). To stop JupyterLab, choose the menu File > Shut Down, or press Ctrl+C twice in the terminal.

Step 7. Or run the notebook without a browser (headless).

In the repository folder, with the environment active, run:

Windows, macOS and Linux:

```
cd Revision/textbook/notebooks
jupyter nbconvert --to notebook --execute --inplace 16a_reference_crosscheck.ipynb
```

This runs every cell from the top to the bottom and saves the results into the notebook file. A failed check stops it with an error message that contains AssertionError and the name of the check. If the command ends with a line that starts with `[NbConvertApp] Writing` and shows no error, every check passed; open the notebook with `jupyter lab 16a_reference_crosscheck.ipynb` (in the same folder, without running the cells again) to read the printed lines and see the figures.

Step 8. What the notebook writes and what you must see.

The notebook writes (or overwrites) these files:

- `Revision/textbook/figures/16a.captions.json`
- `Revision/textbook/figures/16a_1_grid_convergence.png`
- `Revision/textbook/figures/16a_2_uncertainty_validated.png`
- `Revision/textbook/figures/16a_3_eigenvalue_ratios.png`
- `Revision/textbook/figures/16a_4_level_agreement.png`

- `Revision/textbook/figures/16a_5_profile_agreement.png`
- `Revision/textbook/figures/16a_6_uncertainty_budget.png`
- `Revision/textbook/figures/16a_7_ratios_by_class.png`

It changes no other file of the repository except the Rust build folder `target` next to each `Cargo.toml` it builds; running it headless or saving it in JupyterLab also rewrites the notebook file itself. It does not use the internet while it runs. The files it writes are the same files that are stored in the repository (on another computer a figure may differ in a few bytes, which is harmless). To get the stored versions back, run this command in the repository folder (it also undoes every change you made yourself in the folder Revision/textbook):

Windows, macOS and Linux:

```
git checkout -- Revision/textbook
```

Every check of the notebook prints a line that starts with PASS. At the end of the notebook (the output of its last code cell) you must see exactly these lines:

```
PASS every figure file of this notebook exists
ALL 51 CHECKS PASSED (notebook 16a)
```

and the notebook must show 7 figures below the cells that draw them.

Step 9. If something goes wrong.

- "ModuleNotFoundError: No module named ..." in the notebook: JupyterLab was started without the environment. Stop it (menu File > Shut Down), do Step 4, and start it again. If the error remains, another Python installation has registered its own kernel called python3; with the environment active, run the following command and start JupyterLab again:

```
python -m ipykernel install --user --name python3
```

- "FileNotFoundError: The repository folder was not found": the notebook was opened from a copy outside the repository. Open the file `Revision/textbook/notebooks/16a_reference_crosscheck.ipynb` inside the folder Dirac_claude.
- "fatal: destination path 'Dirac_claude' already exists" in Step 3: the repository was downloaded before; skip the line with `git clone`.
- Windows: "running scripts is disabled on this system": run the line with `Set-ExecutionPolicy` and then the activation line again. "py is not recognized": use `python` instead of `py -3`; "python is not recognized": install Python again and tick "Add python.exe to PATH".
- Linux: "ensurepip is not available" when the environment is created: run `sudo apt install python3-venv` and repeat Step 3.

- "jupyter is not recognized" or "command not found: jupyter": the environment is not active; do Step 4. If the environment is active and the message stays, the programs jupyter-lab and jupyter-nbconvert are not in the folders where the terminal looks for programs (`python -m jupyter` does not help then: it has to find the same programs). Start them through Python itself, in the folder of the notebook: the first command below does what `jupyter lab` does, the second what the headless command does:

```
python -m jupyterlab 16a_reference_crosscheck.ipynb
python -m nbconvert --execute --inplace 16a_reference_crosscheck.ipynb
```

- Windows: the headless run prints a RuntimeWarning that mentions the "Proactor event loop" and zmq: this is a message of the package pyzmq, not an error; the run continues normally.
- A red box with "Matplotlib is building the font cache; this may take a moment." in the first run after the installation: this is a message, not an error; the run continues and the message does not come again.
- An AssertionError names a check that failed: choose the menu Kernel > Restart Kernel and Run All Cells; if it fails again, install the packages again with the pip commands of Step 3, because a different package version can change the last digits of a result.
- "cargo is not recognized" or "command not found: cargo" or "cargo was not found": open a new terminal after installing Rust, do Step 4 again, and start JupyterLab from this terminal.
- "linker link.exe not found" (Windows) or "linker cc not found" (Linux): install the C++ Build Tools (Windows) or build-essential (Linux) as described in Step 5 and build again.
- The cell that runs the reference solver on the three ground states shows the label with the star for a minute or longer: this is normal. The state N136_lamp2_a20 alone takes up to two minutes on a fast computer and up to five minutes on a laptop, because the reference solves 354 levels on three grids, each with its excited state and four neighbouring slices. Wait until the label shows a number.
- A line reports that a re-run is not identical byte for byte, but the PASS line after it appears: this is harmless. Another computer may round the last digit of a few numbers differently; the check allows differences of one part in a billion, far below every uncertainty of the record.
- An AssertionError names one of the comparisons with the record: the notebook prints the numbers just above the error. A large difference means that the reference program, the Rust solver or the record was changed. Get the stored versions back and run the notebook again.

```
git checkout -- Revision/kohn_sham
```

- On Windows the cell that builds the Rust solver stops with the cargo message failed to remove file and Access is denied: the program revision_ks_solver is still running in another window or terminal, and Windows does not let cargo replace a running program. Wait until that run has finished (or close it), then run the cell again.

- The run was stopped (by an error, or with Kernel > Interrupt) while the cell that runs the Rust solver was busy: the raw outputs of the Rust runs may then be left behind in a folder whose name starts with textbook_16a_, inside the folder for temporary files of your operating system (in Python, tempfile.gettempdir() names it). The notebook deletes that folder only when the cell finishes. Delete the leftover folder by hand; every run makes a new one.

16.11 Notebook 16a: complete text

This section prints the complete text of the notebook file `Revision/textbook/notebooks/16a_reference_crosscheck.ipynb`: every cell in order, with the output that the stored, executed notebook holds. A text cell (Jupyter calls it a markdown cell) is printed in a frame after the label Text cell. A code cell is printed after the label In [k], where k is the number that Jupyter gives the cell when it runs it; the text that the cell prints follows after the label Out [k], and every figure that the cell draws follows as a figure with its caption.

Text cell:

```
## 1. What this notebook computes

Two different computer programs solve the same Kohn-Sham equations of the fermion
field dirac16complex in the author's primordial gravitational field: the **Rust
solver** (whose results the previous chapter used) and an independent **Python
reference solver**, which shares no code with it and uses a different numerical
method. The **cross-check** compares the two, number by number, with a tolerance rule
that was fixed before any comparison was made. This notebook does that work itself
for a **subset** of five states:

- it runs the reference program of the repository on three ground states and two
  thermal states and checks that the new results reproduce the committed reference
  record;
- it shows how the reference results converge on its three grids, how **Richardson
  extrapolation** removes the grid error and measures what is left, and it tests that
  measured uncertainty on a fourth, finer grid;
- it builds the Rust solver, runs each state twice (with the **canonical** and with
  the **refined** numerics) and measures the Rust uncertainty from the difference;
- it applies the tolerance rule of the cross-check to 5140 comparisons (energies,
  levels, profiles, energy-momentum integrals, adiabaticity, thermodynamics) and
  reproduces the rows and the worst cases of the committed cross-check report;
- it draws seven figures: grid convergence, the fourth-grid test of the uncertainty,
  the convergence ratios of the levels, the agreement of the levels, the agreement
  of a density profile, the uncertainty budget, and all ratios of the subset by
  class.

Four of the five states were chosen because the full cross-check of all 210 states
found its largest differences in them; the fifth (N688_lam0_a00) has the largest
number of particles. The run takes two to six minutes on a fast computer (more
when other programs keep it busy) and about ten minutes on a typical laptop.
```

Text cell:

```
## 2. How to run this notebook
```

Step 1. What this notebook does and what it needs.

Notebook 16a (Running the reference solver on a subset and the cross-check) is the file ‘Revision/textbook/notebooks/16a_reference_crosscheck.ipynb‘ of the repository Dirac_claude. It runs the independent Python reference solver of the repository on five Kohn-Sham states of dirac16complex in the deflating primordial field (three ground states and two thermal states, four of them chosen because the full cross-check found its largest differences there) and on a fourth, finer grid for one state, checks that every new result reproduces the committed reference record, shows how the grids converge and how Richardson extrapolation removes the grid error, builds the Rust solver and runs it with its canonical and its refined numerics to measure its uncertainty, applies the tolerance rule of the cross-check to 5140 comparisons, and reproduces the corresponding rows and worst cases of the committed cross-check report. The raw outputs of the Rust program go into a temporary folder of the operating system (outside the repository), which the notebook deletes as soon as it has read them. It needs a computer with Windows 11, macOS or Linux, an internet connection for the installation, the program Git, and Python 3.12 or newer (the notebooks were built with Python 3.14.5) with these packages at exactly these versions: numpy 2.4.6, sympy 1.14.0, mpmath 1.3.0, matplotlib 3.11.0, jupyterlab 4.4.10, nbformat 5.10.4, nbclient 0.10.2, ipykernel 7.1.0 and nbconvert 7.16.6. The notebook itself imports numpy and matplotlib; the other packages run Jupyter, the program that shows and runs notebooks. It also needs Rust (the program cargo, version 1.91.1 or newer), because it runs the Rust program revision_ks_solver, which is part of the repository and is built on your computer.

Step 2. Install Git and Python (once per computer).

A terminal is the window in which you type commands: on Windows the app Windows PowerShell (or Terminal), on macOS the app Terminal (it runs the shell zsh), on Linux any terminal (it runs the shell bash). Type every command of this section into a terminal exactly as printed, one line at a time, and press Enter after each line.

Windows: download Git from https://git-scm.com/download/win and install it with the default choices. Download Python from https://www.python.org/downloads/ and run the installer; in its first window tick the box "Add python.exe to PATH" before you click "Install Now".

macOS: download Python from https://www.python.org/downloads/ and run the installer. Then open the app Terminal and run this command, which installs Git and the compiler tools:

macOS (zsh):

```
xcode-select --install
```

Linux (Debian or Ubuntu; other distributions have packages of the same names): run these two commands:

Linux (bash):

```
sudo apt update
sudo apt install git python3 python3-venv
```

Then close the terminal and open a NEW one (a terminal opened before the installation does not know the new programs), and check the version of Python; it must print 3.12 or a

higher number:

Windows (PowerShell):

```
    py -3 --version
```

macOS (zsh) and Linux (bash):

```
    python3 --version
```

If an older Linux prints a lower number (Ubuntu 22.04 has Python 3.10), install Python 3.12 with the following three commands, and in Step 3 type ‘python3.12‘ instead of ‘python3‘ in the command that creates the environment:

Linux (bash), only when the version is too low:

```
    sudo add-apt-repository ppa:deadsnakes/ppa
    sudo apt update
    sudo apt install python3.12 python3.12-venv
```

Step 3. Get the repository and install the packages (once per computer).

The commands below download the repository (a few hundred megabytes; the folder then needs up to about 1 GB of disk space) into the folder Dirac_claude inside your home folder, create a private Python environment in the folder dirac-book-env inside your home folder (a private environment is a folder with its own copy of Python and of the packages, so that nothing else on your computer is changed), activate it (from then on the commands ‘python‘ and ‘jupyter‘ typed in this terminal are those of the environment, and the prompt starts with (dirac-book-env)), and install the packages at the pinned versions (this downloads about 90 MB and takes a few minutes; the environment takes about 400 MB of disk space). If you have done this step before, for this or for another notebook, skip it and go to Step 4; to get the newest version of the repository, run ‘git pull‘ in the repository folder after Step 4.

Windows (PowerShell):

```
    cd $HOME
    git clone https://github.com/once-ere/Dirac_claude.git
    py -3 -m venv "$HOME\dirac-book-env"
    Set-ExecutionPolicy -ExecutionPolicy RemoteSigned -Scope Process -Force
    & "$HOME\dirac-book-env\Scripts\Activate.ps1"
    python -m pip install --upgrade pip
    python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
    python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
    python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
```

The line with ‘Set-ExecutionPolicy‘ allows PowerShell to run the activation script in this one window only; it changes nothing permanently.

macOS (zsh):

```
    cd ~
    git clone https://github.com/once-ere/Dirac_claude.git
    python3 -m venv ~/dirac-book-env
```

```
    source ~/dirac-book-env/bin/activate
    python -m pip install --upgrade pip
    python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
    python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
    python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
```

Linux (bash):

```
    cd ~
    git clone https://github.com/once-ere/Dirac_claude.git
    python3 -m venv ~/dirac-book-env
    source ~/dirac-book-env/bin/activate
    python -m pip install --upgrade pip
    python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
    python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
    python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
```

Step 4. In every new terminal: activate the environment and go into the repository folder.

Every later step starts in the repository folder with the environment active. Run these lines whenever you open a new terminal (they do no harm if the environment is already active):

Windows (PowerShell):

```
    Set-ExecutionPolicy -ExecutionPolicy RemoteSigned -Scope Process -Force
    & "$HOME\dirac-book-env\Scripts\Activate.ps1"
    cd "$HOME\Dirac_claude"
```

macOS (zsh) and Linux (bash):

```
    source ~/dirac-book-env/bin/activate
    cd ~/Dirac_claude
```

Step 5. Install Rust and build the Rust program (Rust once per computer, the build once per program).

Windows: download ‘rustup-init.exe‘ from https://rustup.rs, run it and accept the default choices; if it reports that the Visual Studio C++ Build Tools are missing, let it install them (or install the workload "Desktop development with C++" from https://visualstudio.microsoft.com/visual-cpp-build-tools/ and run ‘rustup-init.exe‘ again). macOS and Linux: run the command below and accept the default choice (on Linux first run ‘sudo apt install build-essential‘, which provides the linker that Rust needs).

macOS (zsh) and Linux (bash):

```
    curl --proto "=https" --tlsv1.2 -sSf https://sh.rustup.rs | sh
```

Then close the terminal, open a new one, do Step 4 again, and check the version of cargo; it must print 1.91.1 or a newer version:

Windows, macOS and Linux:

```
    cargo --version
```

Build the program with the following command, in the repository folder (the same command on all three systems):

Windows, macOS and Linux:

```
    cargo build --release --manifest-path Revision/kohn_sham/solver/Cargo.toml
```

The first build takes about 1 minute; later builds reuse the result and take a few seconds. The program is then the file ‘Revision/kohn_sham/solver/target/release/revision_ks_solver‘ (on Windows with the ending ‘.exe‘). The notebook runs the same build command itself before it uses the program (it takes a second when the program is up to date), so the notebook also works if you skip this build; building here first shows any problem with Rust before the notebook starts.

Step 6. Run the notebook in JupyterLab.

In the repository folder, with the environment active, run these two lines (the first one goes into the folder of the notebooks):

Windows, macOS and Linux:

```
    cd Revision/textbook/notebooks
    jupyter lab 16a_reference_crosscheck.ipynb
```

JupyterLab opens in your web browser and shows the notebook (if no browser window opens, copy the address that starts with ‘http://localhost:8888/lab‘ from the terminal into the address bar of your browser). The name at the top right of the notebook must read Python 3 (ipykernel). Choose the menu Run > Run All Cells. While a cell runs, the label to its left shows ‘[*]‘; when it has finished, the label shows a number. The notebook has finished when the last code cell shows a number; this takes about 10 minutes on a typical laptop. Scroll to the end and compare the last printed lines with the lines in the step "What the notebook writes and what you must see" below. To keep the results, save the notebook (menu File > Save Notebook). To stop JupyterLab, choose the menu File > Shut Down, or press Ctrl+C twice in the terminal.

Step 7. Or run the notebook without a browser (headless).

In the repository folder, with the environment active, run:

Windows, macOS and Linux:

```
    cd Revision/textbook/notebooks
    jupyter nbconvert --to notebook --execute --inplace 16a_reference_crosscheck.ipynb
```

This runs every cell from the top to the bottom and saves the results into the notebook file. A failed check stops it with an error message that contains AssertionError and the name of the check. If the command ends with a line that starts with ‘[NbConvertApp] Writing‘ and shows no error, every check passed; open the notebook with ‘jupyter lab 16a_reference_crosscheck.ipynb‘ (in the same folder, without running the cells again) to read the printed lines and see the figures.

Step 8. What the notebook writes and what you must see.

The notebook writes (or overwrites) these files:

- ‘Revision/textbook/figures/16a.captions.json‘
- ‘Revision/textbook/figures/16a_1_grid_convergence.png‘
- ‘Revision/textbook/figures/16a_2_uncertainty_validated.png‘
- ‘Revision/textbook/figures/16a_3_eigenvalue_ratios.png‘
- ‘Revision/textbook/figures/16a_4_level_agreement.png‘
- ‘Revision/textbook/figures/16a_5_profile_agreement.png‘
- ‘Revision/textbook/figures/16a_6_uncertainty_budget.png‘
- ‘Revision/textbook/figures/16a_7_ratios_by_class.png‘

It changes no other file of the repository except the Rust build folder ‘target‘ next to each ‘Cargo.toml‘ it builds; running it headless or saving it in JupyterLab also rewrites the notebook file itself. It does not use the internet while it runs. The files it writes are the same files that are stored in the repository (on another computer a figure may differ in a few bytes, which is harmless). To get the stored versions back, run this command in the repository folder (it also undoes every change you made yourself in the folder Revision/textbook):

Windows, macOS and Linux:

```
git checkout -- Revision/textbook
```

Every check of the notebook prints a line that starts with PASS. At the end of the notebook (the output of its last code cell) you must see exactly these lines:

```
PASS every figure file of this notebook exists
ALL 51 CHECKS PASSED (notebook 16a)
```

and the notebook must show 7 figures below the cells that draw them.

Step 9. If something goes wrong.

- "ModuleNotFoundError: No module named ..." in the notebook: JupyterLab was started without the environment. Stop it (menu File > Shut Down), do Step 4, and start it again. If the error remains, another Python installation has registered its own kernel called python3; with the environment active, run the following command and start JupyterLab again:

  ```
  python -m ipykernel install --user --name python3
  ```

- "FileNotFoundError: The repository folder was not found": the notebook was opened from a copy outside the repository. Open the file ‘Revision/textbook/notebooks/16a_reference_crosscheck.ipynb‘ inside the folder Dirac_claude.
- "fatal: destination path ’Dirac_claude’ already exists" in Step 3: the repository was downloaded before; skip the line with ‘git clone‘.
- Windows: "running scripts is disabled on this system": run the line with ‘Set-ExecutionPolicy‘ and then the activation line again. "py is not recognized": use ‘python‘ instead of ‘py -3‘; "python is not recognized": install Python again and tick "Add python.exe to PATH".
- Linux: "ensurepip is not available" when the environment is created: run ‘sudo apt install python3-venv‘ and repeat Step 3.

- "jupyter is not recognized" or "command not found: jupyter": the environment is not active; do Step 4. If the environment is active and the message stays, the programs jupyter-lab and jupyter-nbconvert are not in the folders where the terminal looks for programs (‘python -m jupyter‘ does not help then: it has to find the same programs). Start them through Python itself, in the folder of the notebook: the first command below does what ‘jupyter lab‘ does, the second what the headless command does:

      python -m jupyterlab 16a_reference_crosscheck.ipynb
      python -m nbconvert --execute --inplace 16a_reference_crosscheck.ipynb

- Windows: the headless run prints a RuntimeWarning that mentions the "Proactor event loop" and zmq: this is a message of the package pyzmq, not an error; the run continues normally.
- A red box with "Matplotlib is building the font cache; this may take a moment." in the first run after the installation: this is a message, not an error; the run continues and the message does not come again.
- An AssertionError names a check that failed: choose the menu Kernel > Restart Kernel and Run All Cells; if it fails again, install the packages again with the pip commands of Step 3, because a different package version can change the last digits of a result.
- "cargo is not recognized" or "command not found: cargo" or "cargo was not found": open a new terminal after installing Rust, do Step 4 again, and start JupyterLab from this terminal.
- "linker link.exe not found" (Windows) or "linker cc not found" (Linux): install the C++ Build Tools (Windows) or build-essential (Linux) as described in Step 5 and build again.
- The cell that runs the reference solver on the three ground states shows the label with the star for a minute or longer: this is normal. The state N136_lamp2_a20 alone takes up to two minutes on a fast computer and up to five minutes on a laptop, because the reference solves 354 levels on three grids, each with its excited state and four neighbouring slices. Wait until the label shows a number.
- A line reports that a re-run is not identical byte for byte, but the PASS line after it appears: this is harmless. Another computer may round the last digit of a few numbers differently; the check allows differences of one part in a billion, far below every uncertainty of the record.
- An AssertionError names one of the comparisons with the record: the notebook prints the numbers just above the error. A large difference means that the reference program, the Rust solver or the record was changed. Get the stored versions back and run the notebook again.

      git checkout -- Revision/kohn_sham

- On Windows the cell that builds the Rust solver stops with the cargo message failed to remove file and Access is denied: the program revision_ks_solver is still running in another window or terminal, and Windows does not let cargo replace a running program. Wait until that run has finished (or close it), then run the cell again.
- The run was stopped (by an error, or with Kernel > Interrupt) while the cell that runs the Rust solver was busy: the raw outputs of the Rust runs may then be left behind in a folder whose name starts with textbook_16a_, inside the folder for temporary files of your operating system (in Python, tempfile.gettempdir() names it). The notebook deletes that folder only when the cell finishes. Delete the leftover folder by hand; every run makes a new one.

The first code cell below (the set-up cell) repeats these instructions as comments; then it imports the packages, finds the repository folder and defines the helpers

‘save_figure‘ (saves a figure and shows it), ‘check‘ (stops with an AssertionError when a check fails, prints a PASS line when it passes), ‘report‘ (prints a key number as a RESULT line) and ‘all_checks_passed‘ (prints the last line).

In [1]:

```
# HOW TO RUN NOTEBOOK 16a (the complete instructions)
#
# STEP 1. WHAT THIS NOTEBOOK DOES AND WHAT IT NEEDS.
#
# Notebook 16a (Running the reference solver on a subset and the cross-check) is the file
# Revision/textbook/notebooks/16a_reference_crosscheck.ipynb of the repository
# Dirac_claude. It runs the independent Python reference solver of the repository on five
# Kohn-Sham states of dirac16complex in the deflating primordial field (three ground
# states and two thermal states, four of them chosen because the full cross-check found
# its largest differences there) and on a fourth, finer grid for one state, checks that
# every new result reproduces the committed reference record, shows how the grids
# converge and how Richardson extrapolation removes the grid error, builds the Rust
# solver and runs it with its canonical and its refined numerics to measure its
# uncertainty, applies the tolerance rule of the cross-check to 5140 comparisons, and
# reproduces the corresponding rows and worst cases of the committed cross-check report.
# The raw outputs of the Rust program go into a temporary folder of the operating system
# (outside the repository), which the notebook deletes as soon as it has read them. It
# needs a computer with Windows 11, macOS or Linux, an internet connection for the
# installation, the program Git, and Python 3.12 or newer (the notebooks were built with
# Python 3.14.5) with these packages at exactly these versions: numpy 2.4.6, sympy
# 1.14.0, mpmath 1.3.0, matplotlib 3.11.0, jupyterlab 4.4.10, nbformat 5.10.4, nbclient
# 0.10.2, ipykernel 7.1.0 and nbconvert 7.16.6. The notebook itself imports numpy and
# matplotlib; the other packages run Jupyter, the program that shows and runs notebooks.
# It also needs Rust (the program cargo, version 1.91.1 or newer), because it runs the
# Rust program revision_ks_solver, which is part of the repository and is built on your
# computer.
#
# STEP 2. INSTALL GIT AND PYTHON (ONCE PER COMPUTER).
#
# A terminal is the window in which you type commands: on Windows the app Windows
# PowerShell (or Terminal), on macOS the app Terminal (it runs the shell zsh), on Linux
# any terminal (it runs the shell bash). Type every command of this section into a
# terminal exactly as printed, one line at a time, and press Enter after each line.
#
# Windows: download Git from https://git-scm.com/download/win and install it with the
# default choices. Download Python from https://www.python.org/downloads/ and run the
# installer; in its first window tick the box "Add python.exe to PATH" before you click
# "Install Now".
#
# macOS: download Python from https://www.python.org/downloads/ and run the installer.
# Then open the app Terminal and run this command, which installs Git and the compiler
# tools:
#
# macOS (zsh):
#     xcode-select --install
#
# Linux (Debian or Ubuntu; other distributions have packages of the same names): run
```

```
# these two commands:
#
# Linux (bash):
#     sudo apt update
#     sudo apt install git python3 python3-venv
#
# Then close the terminal and open a NEW one (a terminal opened before the installation
# does not know the new programs), and check the version of Python; it must print 3.12 or
# a higher number:
#
# Windows (PowerShell):
#     py -3 --version
#
# macOS (zsh) and Linux (bash):
#     python3 --version
#
# If an older Linux prints a lower number (Ubuntu 22.04 has Python 3.10), install Python
# 3.12 with the following three commands, and in Step 3 type python3.12 instead of
# python3 in the command that creates the environment:
#
# Linux (bash), only when the version is too low:
#     sudo add-apt-repository ppa:deadsnakes/ppa
#     sudo apt update
#     sudo apt install python3.12 python3.12-venv
#
# STEP 3. GET THE REPOSITORY AND INSTALL THE PACKAGES (ONCE PER COMPUTER).
#
# The commands below download the repository (a few hundred megabytes; the folder then
# needs up to about 1 GB of disk space) into the folder Dirac_claude inside your home
# folder, create a private Python environment in the folder dirac-book-env inside your
# home folder (a private environment is a folder with its own copy of Python and of the
# packages, so that nothing else on your computer is changed), activate it (from then on
# the commands python and jupyter typed in this terminal are those of the environment,
# and the prompt starts with (dirac-book-env)), and install the packages at the pinned
# versions (this downloads about 90 MB and takes a few minutes; the environment takes
# about 400 MB of disk space). If you have done this step before, for this or for another
# notebook, skip it and go to Step 4; to get the newest version of the repository, run
# git pull in the repository folder after Step 4.
#
# Windows (PowerShell):
#     cd $HOME
#     git clone https://github.com/once-ere/Dirac_claude.git
#     py -3 -m venv "$HOME\dirac-book-env"
#     Set-ExecutionPolicy -ExecutionPolicy RemoteSigned -Scope Process -Force
#     & "$HOME\dirac-book-env\Scripts\Activate.ps1"
#     python -m pip install --upgrade pip
#     python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
#     python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
#     python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
#
# The line with Set-ExecutionPolicy allows PowerShell to run the activation script in
# this one window only; it changes nothing permanently.
#
# macOS (zsh):
```

```
#     cd ~
#     git clone https://github.com/once-ere/Dirac_claude.git
#     python3 -m venv ~/dirac-book-env
#     source ~/dirac-book-env/bin/activate
#     python -m pip install --upgrade pip
#     python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
#     python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
#     python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
#
# Linux (bash):
#     cd ~
#     git clone https://github.com/once-ere/Dirac_claude.git
#     python3 -m venv ~/dirac-book-env
#     source ~/dirac-book-env/bin/activate
#     python -m pip install --upgrade pip
#     python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
#     python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
#     python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
#
# STEP 4. IN EVERY NEW TERMINAL: ACTIVATE THE ENVIRONMENT AND GO INTO THE REPOSITORY
# FOLDER.
#
# Every later step starts in the repository folder with the environment active. Run these
# lines whenever you open a new terminal (they do no harm if the environment is already
# active):
#
# Windows (PowerShell):
#     Set-ExecutionPolicy -ExecutionPolicy RemoteSigned -Scope Process -Force
#     & "$HOME\dirac-book-env\Scripts\Activate.ps1"
#     cd "$HOME\Dirac_claude"
#
# macOS (zsh) and Linux (bash):
#     source ~/dirac-book-env/bin/activate
#     cd ~/Dirac_claude
#
# STEP 5. INSTALL RUST AND BUILD THE RUST PROGRAM (RUST ONCE PER COMPUTER, THE BUILD ONCE
# PER PROGRAM).
#
# Windows: download rustup-init.exe from https://rustup.rs, run it and accept the default
# choices; if it reports that the Visual Studio C++ Build Tools are missing, let it
# install them (or install the workload "Desktop development with C++" from
# https://visualstudio.microsoft.com/visual-cpp-build-tools/ and run rustup-init.exe
# again). macOS and Linux: run the command below and accept the default choice (on Linux
# first run sudo apt install build-essential, which provides the linker that Rust needs).
#
# macOS (zsh) and Linux (bash):
#     curl --proto "=https" --tlsv1.2 -sSf https://sh.rustup.rs | sh
#
# Then close the terminal, open a new one, do Step 4 again, and check the version of
# cargo; it must print 1.91.1 or a newer version:
#
# Windows, macOS and Linux:
#     cargo --version
#
```

```
# Build the program with the following command, in the repository folder (the same
# command on all three systems):
#
# Windows, macOS and Linux:
#     cargo build --release --manifest-path Revision/kohn_sham/solver/Cargo.toml
#
# The first build takes about 1 minute; later builds reuse the result and take a few
# seconds. The program is then the file
# Revision/kohn_sham/solver/target/release/revision_ks_solver (on Windows with the ending
# .exe). The notebook runs the same build command itself before it uses the program (it
# takes a second when the program is up to date), so the notebook also works if you skip
# this build; building here first shows any problem with Rust before the notebook starts.
#
# STEP 6. RUN THE NOTEBOOK IN JUPYTERLAB.
#
# In the repository folder, with the environment active, run these two lines (the first
# one goes into the folder of the notebooks):
#
# Windows, macOS and Linux:
#     cd Revision/textbook/notebooks
#     jupyter lab 16a_reference_crosscheck.ipynb
#
# JupyterLab opens in your web browser and shows the notebook (if no browser window
# opens, copy the address that starts with http://localhost:8888/lab from the terminal
# into the address bar of your browser). The name at the top right of the notebook must
# read Python 3 (ipykernel). Choose the menu Run > Run All Cells. While a cell runs, the
# label to its left shows [*]; when it has finished, the label shows a number. The
# notebook has finished when the last code cell shows a number; this takes about 10
# minutes on a typical laptop. Scroll to the end and compare the last printed lines with
# the lines in the step "What the notebook writes and what you must see" below. To keep
# the results, save the notebook (menu File > Save Notebook). To stop JupyterLab, choose
# the menu File > Shut Down, or press Ctrl+C twice in the terminal.
#
# STEP 7. OR RUN THE NOTEBOOK WITHOUT A BROWSER (HEADLESS).
#
# In the repository folder, with the environment active, run:
#
# Windows, macOS and Linux:
#     cd Revision/textbook/notebooks
#     jupyter nbconvert --to notebook --execute --inplace 16a_reference_crosscheck.ipynb
#
# This runs every cell from the top to the bottom and saves the results into the notebook
# file. A failed check stops it with an error message that contains AssertionError and
# the name of the check. If the command ends with a line that starts with [NbConvertApp]
# Writing and shows no error, every check passed; open the notebook with jupyter lab
# 16a_reference_crosscheck.ipynb (in the same folder, without running the cells again) to
# read the printed lines and see the figures.
#
# STEP 8. WHAT THE NOTEBOOK WRITES AND WHAT YOU MUST SEE.
#
# The notebook writes (or overwrites) these files:
#
# - Revision/textbook/figures/16a.captions.json
# - Revision/textbook/figures/16a_1_grid_convergence.png
```

```
# - Revision/textbook/figures/16a_2_uncertainty_validated.png
# - Revision/textbook/figures/16a_3_eigenvalue_ratios.png
# - Revision/textbook/figures/16a_4_level_agreement.png
# - Revision/textbook/figures/16a_5_profile_agreement.png
# - Revision/textbook/figures/16a_6_uncertainty_budget.png
# - Revision/textbook/figures/16a_7_ratios_by_class.png
#
# It changes no other file of the repository except the Rust build folder target next to
# each Cargo.toml it builds; running it headless or saving it in JupyterLab also rewrites
# the notebook file itself. It does not use the internet while it runs. The files it
# writes are the same files that are stored in the repository (on another computer a
# figure may differ in a few bytes, which is harmless). To get the stored versions back,
# run this command in the repository folder (it also undoes every change you made
# yourself in the folder Revision/textbook):
#
# Windows, macOS and Linux:
#     git checkout -- Revision/textbook
#
# Every check of the notebook prints a line that starts with PASS. At the end of the
# notebook (the output of its last code cell) you must see exactly these lines:
#
#     PASS every figure file of this notebook exists
#     ALL 51 CHECKS PASSED (notebook 16a)
#
# and the notebook must show 7 figures below the cells that draw them.
#
# STEP 9. IF SOMETHING GOES WRONG.
#
# - "ModuleNotFoundError: No module named ..." in the notebook: JupyterLab was started
#   without the environment. Stop it (menu File > Shut Down), do Step 4, and start it
#   again. If the error remains, another Python installation has registered its own
#   kernel called python3; with the environment active, run the following command and
#   start JupyterLab again:
#     python -m ipykernel install --user --name python3
# - "FileNotFoundError: The repository folder was not found": the notebook was opened
#   from a copy outside the repository. Open the file
#   Revision/textbook/notebooks/16a_reference_crosscheck.ipynb inside the folder
#   Dirac_claude.
# - "fatal: destination path 'Dirac_claude' already exists" in Step 3: the repository was
#   downloaded before; skip the line with git clone.
# - Windows: "running scripts is disabled on this system": run the line with
#   Set-ExecutionPolicy and then the activation line again. "py is not recognized": use
#   python instead of py -3; "python is not recognized": install Python again and tick
#   "Add python.exe to PATH".
# - Linux: "ensurepip is not available" when the environment is created: run sudo apt
#   install python3-venv and repeat Step 3.
# - "jupyter is not recognized" or "command not found: jupyter": the environment is not
#   active; do Step 4. If the environment is active and the message stays, the programs
#   jupyter-lab and jupyter-nbconvert are not in the folders where the terminal looks for
#   programs (python -m jupyter does not help then: it has to find the same programs).
#   Start them through Python itself, in the folder of the notebook: the first command
#   below does what jupyter lab does, the second what the headless command does:
#     python -m jupyterlab 16a_reference_crosscheck.ipynb
#     python -m nbconvert --execute --inplace 16a_reference_crosscheck.ipynb
```

```
# - Windows: the headless run prints a RuntimeWarning that mentions the "Proactor event
#   loop" and zmq: this is a message of the package pyzmq, not an error; the run
#   continues normally.
# - A red box with "Matplotlib is building the font cache; this may take a moment." in
#   the first run after the installation: this is a message, not an error; the run
#   continues and the message does not come again.
# - An AssertionError names a check that failed: choose the menu Kernel > Restart Kernel
#   and Run All Cells; if it fails again, install the packages again with the pip
#   commands of Step 3, because a different package version can change the last digits of
#   a result.
# - "cargo is not recognized" or "command not found: cargo" or "cargo was not found":
#   open a new terminal after installing Rust, do Step 4 again, and start JupyterLab from
#   this terminal.
# - "linker link.exe not found" (Windows) or "linker cc not found" (Linux): install the
#   C++ Build Tools (Windows) or build-essential (Linux) as described in Step 5 and build
#   again.
# - The cell that runs the reference solver on the three ground states shows the label
#   with the star for a minute or longer: this is normal. The state N136_lamp2_a20 alone
#   takes up to two minutes on a fast computer and up to five minutes on a laptop,
#   because the reference solves 354 levels on three grids, each with its excited state
#   and four neighbouring slices. Wait until the label shows a number.
# - A line reports that a re-run is not identical byte for byte, but the PASS line after
#   it appears: this is harmless. Another computer may round the last digit of a few
#   numbers differently; the check allows differences of one part in a billion, far below
#   every uncertainty of the record.
# - An AssertionError names one of the comparisons with the record: the notebook prints
#   the numbers just above the error. A large difference means that the reference
#   program, the Rust solver or the record was changed. Get the stored versions back and
#   run the notebook again.
#     git checkout -- Revision/kohn_sham
# - On Windows the cell that builds the Rust solver stops with the cargo message failed
#   to remove file and Access is denied: the program revision_ks_solver is still running
#   in another window or terminal, and Windows does not let cargo replace a running
#   program. Wait until that run has finished (or close it), then run the cell again.
# - The run was stopped (by an error, or with Kernel > Interrupt) while the cell that
#   runs the Rust solver was busy: the raw outputs of the Rust runs may then be left
#   behind in a folder whose name starts with textbook_16a_, inside the folder for
#   temporary files of your operating system (in Python, tempfile.gettempdir() names it).
#   The notebook deletes that folder only when the cell finishes. Delete the leftover
#   folder by hand; every run makes a new one.
#
# ------------------------------------------------------------------------------------
# ====================================================================================
# THE SET-UP (the same in every notebook of this book; it computes no physics)
# ====================================================================================
import json  # reads and writes JSON files (text files that hold names and numbers)

## 3. The words used in this notebook

- **Solver**: a program that computes the solution of equations. The **Rust solver**
  integrates the orbital equation step by step from one end of the hidden coordinate
  to the other (*shooting*). The **reference solver** writes the same equation as one
  large matrix on a grid and finds its eigenvalues.
- **Grid**: equally spaced points on the interval $-L \le y \le 0$. $G$ is the number
  of cells, $h = L/G$ the width of one cell. The reference uses $G = 300$, $600$ and
  $1200$; one state is also solved on $G = 2400$ (the **fourth grid**).
- **Grid error**: the difference between a number computed on a grid and the exact
  number. For the reference it shrinks like $h^2$.
- **Richardson extrapolation**: a combination of the results on several grids in
  which the leading grid errors cancel. $R$ is the extrapolated value, $U$ its
  measured **uncertainty** (how far it may still be from the exact value).
- **Validation**: a test of a stated uncertainty against a more accurate number.
- **Canonical numerics** of the Rust solver: $G = 900$ RK4 steps and its standard
  tolerances. **Refined numerics**: $G = 1800$ steps and ten times smaller
  tolerances. $U_{Rust}$ is the uncertainty of the canonical Rust result measured
  from the two.
- **Tolerance**: the largest difference allowed between the two solvers.
  **Ratio**: the difference divided by the tolerance; a comparison passes when the
```

```
  ratio is at most 1.
- **State id**: a name such as `N136_lamp2_a20`: $N = 136$ particles, coupling
  $+\lambda_2$ (`lam0`: $\lambda = 0$; `lamp1`, `lamm1`: $\pm\lambda_1$; `lamp2`,
  `lamm2`: $\pm\lambda_2$), slice $a_{4,0} = 2.0$ (the digits are ten times
  $a_{4,0}$). A thermal state ends with `_T10`, `_T20` or `_T50`: the temperature
  $T = 0.01$, $0.02$ or $0.05$ (in units of the mass $m$).
- **Level key** `n2:j:parity:rank`: the shell $n_2 = |\vec n|^2$ of the 3-space
  momentum, the block type $j = \pm 1$, the brane parity (even or odd), and the
  **rank**, the position of the level among the particle levels of its sector
  (0 = the lowest). The Rust solver numbers levels by a **label**; the rank is the
  label minus the label of the lowest particle level (`label_min`).
- **Profile**: a density as a function of $y$, stored at the 151 points
  $y = -3 + 0.02\,i$. **Brane value** and **tip value**: its values at $y = 0$ and
  $y = -3$.
- **JSON** and **CSV**: two text formats for stored numbers (JSON: named entries in
  braces; CSV: a table, one line per row, entries separated by commas).
- **Record**: a committed Revision file whose numbers this notebook reproduces.
  **Byte for byte identical**: two files that agree in every character.
- $E_{KS}$: the Kohn-Sham energy; $E_{band} = \sum g f \varepsilon$ the sum of the
  occupied levels; $E_{int}$ the interaction energy; $E_{KS} = E_{band} - E_{int}$.
  **HOMO**, **LUMO**: the highest occupied and lowest unoccupied level; the
  **KS gap** is their difference. **Delta-SCF**: the energy of the first excited
  state minus $E_{KS}$.
- $\int\rho$, $\int p_3$, $\int p_t$, $\int p_0$, $\int n$: the energy density, the
  three pressures and the particle density integrated over the hidden coordinate
  with the volume factor, $2\,\mathrm{Vol}_7 \int_{-L}^{0} e^{6Hy}(\dots)\,dy$.
- $dE/da_4$: how fast the energy changes along the history; $Q_{max}$: the
  **adiabaticity** measure (small means the slow-change approximation holds);
  $\Delta E_x$: the difference between the exact Fock exchange and the uniform-gas
  exchange.
- $\mu$, $E$, $S$, $F = E - TS$, $\Omega$: chemical potential, energy, entropy, free
  energy and grand potential of a thermal state; $C_V = T\,dS/dT$ its heat capacity.
```

Text cell:

```
## 4. The physical and mathematical situation

**The equations being solved.** The author's coordinates are $x_1, x_2, x_3$
(3-space, scale factor $e^{a_4} \sin^{1/6} z$), $x_4$ (the time), $x_5, x_6, x_7$
(the three extra times, which DEFLATE exponentially: scale factor
$e^{-a_4} \sin^{1/6} z$ with $a_4$ increasing) and $x_0$ (the hidden direction,
$z = 6Hx_0$, written through $y = \ln(\sin z)/(6H)$ in $-L \le y \le 0$). Along the
PRESCRIBED BACKGROUND history $a_4 = A H x_4$ ($A = 1$) the Kohn-Sham states are
computed at five instants, the **slices** $a_{4,0} = 0, 0.5, 1, 1.5, 2$. At a slice
each orbital $\chi(y)$ solves the $2\times 2$ block equation
$$h_j\,\chi = \varepsilon\,\chi, \qquad h_j = j\left[-i\sigma_1 \frac{d}{dy}
+ M\sigma_2 + \kappa k\,\sigma_3\right] + v, \qquad \kappa = e^{-Hy - a_{4,0}},$$
with the ASSUMED $Z_2$ brane at $y = 0$, a regular tip at $y = -L = -3$, and the
self-consistent potentials $M = m + \tfrac{15}{16}\lambda S$ and
$v = -\tfrac{1}{16}\lambda n$ (units $H = m = 1$).

**Two independent solvers.** The Rust solver shoots with RK4 ($G = 900$ steps); the
reference solver puts the two components of $\chi$ on a staggered grid, turns the
```

```
equation into a symmetric matrix of size $2G - 1$, and computes every quantity on
$G = 300$, $600$ and $1200$. Its error behaves like $c\,h^2 + d\,h^4 + \dots$, so the
Richardson value
$$R = \frac{64\,x(1200) - 20\,x(600) + x(300)}{45}$$
removes the $h^2$ and $h^4$ terms, and its uncertainty is
$U_{ref} = |R - (4\,x(1200) - x(600))/3| + 2\cdot 10^{-12}\max(1, |R|)$.

**The Rust uncertainty.** RK4 has errors of order $h^4$. Halving the step divides
the error $e$ by $2^4 = 16$, so canonical minus refined is $e - e/16 = \tfrac{15}{16}e$
and the canonical error is $e = \tfrac{16}{15}\,|x_{canonical} - x_{refined}|$. This
is $U_{Rust}$.

**The tolerance rule** (fixed in the cross-check program before any comparison):
$$|x_{Rust} - x_{ref}| \le 3\,(U_{ref} + U_{Rust}) + 10^{-12}\cdot\text{scale},$$
with scale $= \max(1, |x|)$ for single numbers and the largest value of the profile
for profile points. The **ratio** is the left side divided by the right side.

**The subset.** The committed cross-check compared all 210 states (75 ground, 135
thermal) and passed all 31 checks. This notebook recomputes five of them:

| state | $N$ | $\lambda$ | $a_{4,0}$ | $T$ | why it is in the subset |
| --- | --- | --- | --- | --- | --- |
| N8_lamm2_a00 | 8 | $-\lambda_2$ | 0 | 0 | largest ratio of all, at the tip |
| N688_lam0_a00 | 688 | 0 | 0 | 0 | the largest number of particles |
| N136_lamp2_a20 | 136 | $+\lambda_2$ | 2 | 0 | largest ratios of levels and $Q_{max}$ |
| N8_lamm1_a00_T10 | 8 | $-\lambda_1$ | 0 | 0.01 | where the first cross-check failed |
| N8_lam0_a15_T50 | 8 | 0 | 1.5 | 0.05 | largest thermal ratios |

The values of $\lambda_1$ and $\lambda_2$ depend on $N$; the next cells read them.
What the cross-check can and cannot show is said at the end of the notebook.
```

Text cell:

```
## 5. The records and the problem definition of both solvers

The next cell reads the three committed reports (reference, Rust solver,
cross-check) and checks that every check in them passed. Then it compares the
problem definitions in the two ‘parameters.json‘ files (the physical constants
$H$, $m$, $L$, $\Delta k$, $v_t$, the tip angle, the history, the slices, the
temperatures, and the fingerprint of the theory file both programs read) and the
six couplings that each solver derived on its own from the same rule. This repeats
the cross-check’s checks ‘problem_definition_identical‘ and (for the couplings)
‘parameters_couplings‘. It also prints the sizes of the two checks that the
cross-check gained on 2026-10-08: ‘thermo_levels‘ (every level of every thermal
state, label by label) and ‘thermo_mu_rust_stated_bound‘ (the Rust solver’s stated
rounding bound of $\mu$, tested against roots computed with 40 digits).

## 6. The reference program and the five states

The reference program is the Python file ‘Revision/kohn_sham/reference/run_reference.py‘
(it uses ‘ks_fd.py‘ in the same folder). Its **jobs** compute one state each: a
ground-state job solves the state, its Delta-SCF excited state, four neighbouring
slices $a_{4,0} \pm 0.002$, $\pm 0.004$ (for $dE/da_4$ and the adiabaticity
measure) and its particle-hole list, all on the three grids; a thermal job solves the
state and four neighbouring temperatures $T(1 \pm 0.01)$, $T(1 \pm 0.02)$ (for
$C_V$). The next cell makes Python find the program, imports it **without running
it** (importing only defines its functions), reads the functional coefficients it
takes from ‘ks-theory.json‘, and writes down the five states as the program’s job
```

```
descriptions: the id, $N$, the coupling tag and value, the slice, the first-order
mean-field size $\sigma$ (0, 0.1 or 0.3; it sets how many levels are kept), and the
temperature.
```

In [3]:

Text cell:

7. Running the reference solver on the three ground states

The next cell runs the reference program's ground-state job for each of the three ground states. One addition: the job calls the program's function `_ground_on_grid` once for each grid and keeps only the extrapolated levels. To draw the convergence of every level we want the levels on each grid as well, so the cell **wraps** that function: it puts in its place a small function of our own that calls the original one, keeps a copy of the levels it returns, and passes its result on unchanged. After the three jobs the original function is put back. The results are the contents of the JSON files the reference program writes (`RR.jsonable` turns the arrays into plain numbers, as the program does before it writes a file). This cell takes one to three minutes on a fast computer.

Text cell:

The next cell compares each new result with the committed file `Revision/kohn_sham/reference/results/ground/<id>.json`. The function `compare_records` walks through both structures at the same time: the same names in every dictionary, the same length of every list, the same texts and truth values, and every number equal within one part in a billion (10^{-9} relative). It counts the numbers it compared. The function `check_reproduction` also writes the new

result as text exactly as the reference program writes its files and reports
whether that text is identical to the committed file **byte for byte** (on the
computer that built this book it is; the cross-check's own repeat run found the
same for all 340 files).

In [5]:

## 8. Richardson extrapolation at work

Write $x(h)$ for a number computed on a grid with cell width $h$ and $X$ for its exact
value. For the staggered grid the error has only even powers of $h$:
$$x(h) = X + c\,h^2 + d\,h^4 + \dots$$
The three grids have $h$, $h/2$ and $h/4$ ($G = 300$, $600$, $1200$). Line by line:

- Halving $h$ gives $x(h/2) = X + c\,h^2/4 + d\,h^4/16 + \dots$ (put $h/2$ in place of
  $h$).
- Then $4\,x(h/2) - x(h) = 3X + (4/16 - 1)\,d\,h^4 + \dots$ (the $c\,h^2$ terms cancel,
  because $4 \cdot c h^2/4 = c h^2$).
- So $r(h) = \frac{4\,x(h/2) - x(h)}{3} = X - \frac{d\,h^4}{4} + \dots$: one
  Richardson step leaves an $h^4$ error.
- The same step on the finer pair gives $r(h/2) = X - \frac{d\,h^4}{64} + \dots$.
- Then $\frac{16\,r(h/2) - r(h)}{15} = X + \dots$ (the $h^4$ terms cancel, because
  $16/64 = 1/4$), and multiplying out gives
  $R = \frac{64\,x(h/4) - 20\,x(h/2) + x(h)}{45}$.
- The leftover error of the finest one-step value $r(h/2)$ is about $|R - r(h/2)|$;
  that is the uncertainty $U$ (plus a floor $2\cdot 10^{-12}\max(1,|R|)$ for
  rounding). Because $R$ has removed one more error term than $r(h/2)$, $U$ is meant
  to over-estimate the error of $R$; section 9 tests this on a fourth grid.
- Because $x(h) - x(h/2) \approx \tfrac34 c h^2$ and
  $x(h/2) - x(h/4) \approx \tfrac{3}{16} c h^2$, their **ratio is 4** when the grids
  are fine enough for the $h^2$ term to dominate (the *asymptotic regime*).

The next cell prints $E_{KS}$ of each ground state on the three grids, computes $R$
and $U$ with our own lines (both written forms of $R$), checks that they equal the
values in the reference result, and prints the ratio of the differences.
```

In [6]:

## 9. A fourth grid tests the uncertainty

Is $U$ really larger than the error of $R$? The reference program answers this with
its job ‘validation_job‘: it solves one state, N136_lamp2_a20 (the strongest coupling
with the largest densities at the tip), on four grids $G = 300, 600, 1200, 2400$,
forms the three-grid value twice, $R_{123}$ from $(300, 600, 1200)$ and $R_{234}$
from $(600, 1200, 2400)$, and compares $|R_{123} - R_{234}|$ with the stated
uncertainty $U_{123}$ for 19 classes of quantities (energies, HOMO, LUMO, integrals,
tip and brane values, all levels, five profiles). $R_{234}$ is much closer to the
exact value than $R_{123}$ (its grids are twice as fine and its leftover error
shrinks like $h^6$), so $|R_{123} - R_{234}|$ is practically the error of $R_{123}$.

The next cell runs that job again (about 40 seconds) and compares its result with the
committed file ‘Revision/kohn_sham/reference/results/validation/N136_lamp2_a20.json‘.
To draw the four grids we again use a wrapper: the job calls the function
```

‘observables‘ of ‘ks_fd‘ once on each grid, and our wrapper keeps E_{KS}, the
levels and the tip value of p_0 of each grid.

In [7]:

```
FOUR_GRIDS = {}  # G -> (E_KS, levels, p0 at the tip) of N136_lamp2_a20 on grid G

PASS the errors shrink grid by grid and R123 lies within U123 of R234
```

Text cell:

```
The next figure draws the result of the validation for all 19 classes: for each
class the largest value of $|R_{123} - R_{234}|/U_{123}$ over its elements. A bar
that stays left of the line 1 means that the stated uncertainty covers the change.
A class whose largest value is exactly zero (the two three-grid values agree in every
digit) is drawn at $10^{-8}$.
```

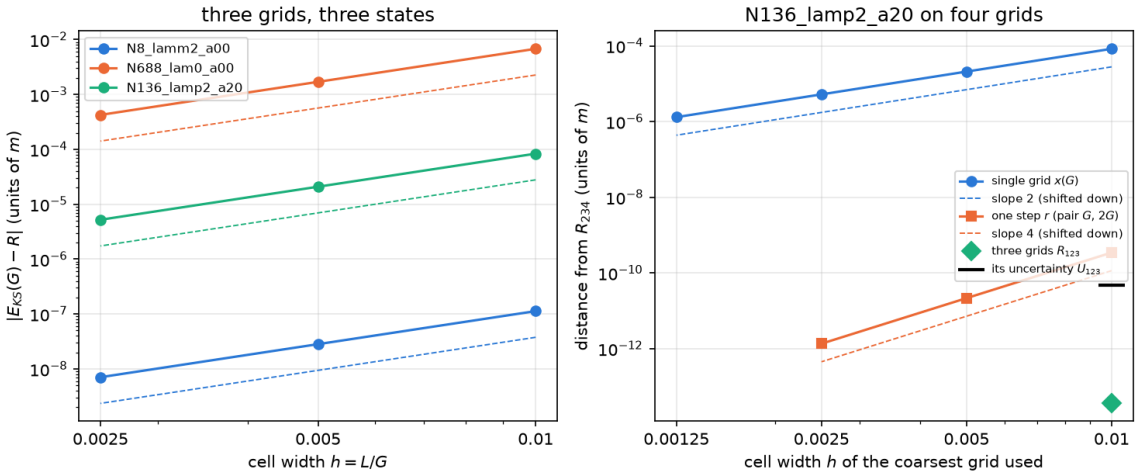

Figure 439: Convergence of the reference solver for the Kohn-Sham energy E_{KS}, logarithmic axes, energies in units of the mass m. Left: distance of the single-grid value from the Richardson value R against the cell width $h = 3/G$ for $G = 300, 600, 1200$ for the three ground states; the points run parallel to the dashed lines of slope 2 (drawn a factor 3 lower), an error proportional to h^2. Right: the state N136_lamp2_a20 also on $G = 2400$, every distance measured from the four-grid best value R_{234}: single grids fall with slope 2, one Richardson step with slope 4, and the three-grid value R_{123} (diamond) lies far below its stated uncertainty U_{123} (bar), so U is a safe over-estimate. (Notebook 16a, figure 1.)

## 10. Every level converges like $h^2$

The ratio test can be made for every level, not only for $E_{KS}$. The next cell
computes, for every level of the three ground states, the ratio
$(x(300) - x(600))/(x(600) - x(1200))$ with the reference program's own function
`RR.asym_ratio` (it leaves out levels whose differences are below $10^{-10}$, where
rounding would dominate), and compares the median, smallest and largest ratio with
```

the values stored in the record (entry ‘consistency‘). Then it draws, for every level, the distance of its ratio from 4 against the level’s energy. The reference’s check ‘richardson_asymptotic_ratio‘ requires the median to lie within 0.05 of 4.

In [10]:

```
level_points = []  # (state, level energy, ratio) of every level with a ratio

## 12. The Rust solver: canonical and refined runs

The next cell builds the Rust solver with cargo (a second when it is already built)
and runs its command `single` for each state twice: with the canonical numerics and
with `--refined`. The arguments are exactly those of the cross-check's measurement
program `measure_rust_refinement.py`: the mass $m = 1$, the coupling, the slice, $N$,
the temperature for thermal states, and the **margin**, which decides how many levels
above the Fermi level are kept ($0.25 + 2\sigma$ at $T = 0$, $0.2 + 2\sigma$ at
$T > 0$). Each run writes a JSON file (energies, levels, integrals) and a CSV file
(the profiles) into a new **temporary folder** of the operating system, outside the
repository; the cell reads them back and then deletes the folder, so the runs leave
no file behind. It prints each command without the two output-file options (their
folder differs from run to run).
```

In [12]:

```
SOLVER = rust_program(f"{KS}/solver/Cargo.toml", "revision_ks_solver")
RUN_FOLDER = Path(tempfile.mkdtemp(prefix="textbook_16a_"))  # a new, empty folder

def run_single(sid, refined):
    """Run ‘revision_ks_solver single‘ for state sid; return (results, profiles,
    the arguments without the output files)."""
    spec = SPECS[sid]
    margin = (0.2 if "T" in spec else 0.25) + 2.0 * spec["sigma"]
    stem = f"{sid}_{’refined’ if refined else ’canonical’}"
    arguments = ["single", "--m", "1", "--lambda", repr(spec["lam"]),
                 "--a4", repr(spec["a4"]), "--N", repr(spec["N"]),
                 "--margin", repr(margin)]
    if "T" in spec:
        arguments += ["--T", repr(spec["T"])]
    if refined:
        arguments.append("--refined")
    files = ["--out", f"{RUN_FOLDER / stem}.json",
             "--profiles", f"{RUN_FOLDER / stem}.csv"]
    done = subprocess.run([str(SOLVER)] + arguments + files, cwd=str(REPO),
                          capture_output=True, text=True)
    if done.returncode != 0 or not done.stdout.strip().endswith("SUCCESS"):
        print(done.stderr[-2000:])
        raise RuntimeError(f"the Rust run {stem} failed")
    results = json.loads((RUN_FOLDER / f"{stem}.json").read_text(encoding="utf-8"))
    with open(RUN_FOLDER / f"{stem}.csv", newline="", encoding="utf-8") as handle:
        profiles = [{k: float(v) for k, v in row.items()}
                    for row in csv.DictReader(handle)]
    return results, profiles, arguments

    --refined
PASS ten Rust runs (five states, two numerics) completed
```

Text cell:

```
The measured differences are only meaningful if the canonical ‘single‘ run gives
exactly the committed canonical results. The next cell checks this, as the
cross-check’s check ‘rust_refinement_applies_to_matrix‘ does: for the ground states
$E_{KS}$, the five energy-momentum integrals, every level and every profile point;
for the thermal states $E$, $\mu$ and the entropy; each must agree with the committed
files within $10^{-12}$ (relative to $\max(1,|x|)$ or to the profile’s largest value).
Then it computes the canonical-minus-refined differences of $E_{KS}$, of the levels and
(for thermal states) of $\mu$ and checks that they equal the values recorded in
‘Revision/kohn_sham/checker/rust-refinement.json‘.
```

## 13. The tolerance rule in a few lines of Python

The next cell writes the rule as a function. ‘compare‘ receives the class, the case
name, the Rust value, the reference value, the two uncertainties and (for profile
points) the scale; it computes the tolerance and the ratio exactly as the cross-check
program does and stores a row in the list ‘ROWS‘. The cell also computes, for every
state, the Rust uncertainties $U_{Rust} = \tfrac{16}{15}|canonical - refined|$ of
every quantity the ‘single‘ command reports, and reads the **matrix-wide** Rust
uncertainties that the cross-check uses for quantities that ‘single‘ does not report
(Delta-SCF, $Q_{max}$, $dE/da_4$ by differences, $C_V$); they are the largest
canonical-minus-refined differences of the whole Rust matrix, recorded in the
cross-check report. Finally it shows every piece of one comparison, $E_{KS}$ of
N8_lamm2_a00.
```

In [14]:

Text cell:

14. The ground-state comparisons

The next cell makes, for the three ground states, the comparisons of the cross-check program's ground-state classes (the class names are the names of its checks):

- `ground_energies`: E_{KS}, E_{band}, E_{int} with U_{Rust} measured;
- `ground_homo_lumo_gap`: HOMO and LUMO with U_{Rust} = the largest level uncertainty of the state, the gap with twice that;
- `ground_eigenvalues`: every level present in both label sets, key by key (a Rust label is turned into a rank by subtracting `label_min`);
- `excited_delta_scf`: Delta-SCF and $E_{excited}$, with the matrix-wide Delta-SCF uncertainty;
- `ground_occupations_and_groups` (not a ratio): the same occupied levels.

The uncertainties were measured in the cells above. The comparisons of the energy-momentum tensor follow in the cell after this one.

In [15]:

```
def rank_key(n2, j, parity, rank):
    """The level key n2:j:parity:rank as a text, for example 1:-1:even:2."""

Text cell:

```
The next cell adds the comparisons of the energy-momentum tensor and of the
adiabaticity, again in the classes of the cross-check program:

- ‘emt_integrals‘: the five integrals $\int\rho$, $\int p_3$, $\int p_t$, $\int p_0$,
  $\int n$;
- ‘emt_brane_tip_values‘: $\rho$, $p_3$, $p_t$, $p_0$ at the brane and at the tip;
- ‘ground_profiles‘: the ten profiles at all 151 points, with the scale = the
  largest value of the profile;
- ‘exchange_delta_E_x‘: $\Delta E_x$, whose Rust uncertainty is derived from the
  measured uncertainty of the profile $Q$ (twice its relative size, because
  $\Delta E_x$ is quadratic in $Q$);
- ‘adiabatic_dE_da4‘: $dE/da_4$ in its energy-momentum form (uncertainty from the
  integrals of $p_3$ and $p_t$) and as a difference quotient (matrix-wide);
- ‘adiabatic_Q_max‘: $Q_{max}$, and when it is not zero also its matrix element and
  its level spacing; the maximising pair of levels must be the same.

The pair of levels of $Q_{max}$ is printed with the Rust labels and the reference
ranks; for the sector of that pair (even parity, $j = +1$) the lowest particle label
is 0, so labels and ranks coincide.
```

## 15. The thermal comparisons

The next cell makes the thermal comparisons of the two thermal states, in the
cross-check classes ‘thermo_state_functions‘ ($\mu$, $E$, $S$, $F$, $\Omega$ in both
of its forms) and ‘thermo_derivatives‘ ($C_V = T\,dS/dT$, $dE/dT$, $-dF/dT$). The
Rust uncertainties of $F = E - TS$ and $\Omega = F - \mu N$ are added up from those
of $E$, $S$ and $\mu$ ($U_F = U_E + T U_S$, $U_\Omega = U_F + N U_\mu$). $dE/dT$ and
$-dF/dT$ are difference quotients of energies over $dT = 0.01\,T$, so each solver’s
noise floor is added: $N \times$ (the Rust root tolerance $10^{-13}$) $/dT$ and
$N \times 10^{-12}/dT$ for the reference.

Three classes of the full cross-check are not repeated here: the particle-hole
lists, the exact-Fock variant and the rescaling partners (other solver runs that this
subset does not make), and for thermal states the sea-hole diagnostic and the
40-digit chemical potential (Notebook 16c computes the latter for all 45 thermal
states with $N = 8$, among them N8_lamm1_a00_T10).

## 16. Reproducing the committed cross-check report

The cross-check program wrote every comparison of single numbers into the table
‘Revision/kohn_sham/reports/ks-crosscheck-table.csv‘ (levels and profile points are
too many; the report keeps only their worst case). The next cell finds every one of
our comparisons in that table and checks that our tolerance and ratio agree with the
stored ones to the four significant digits the table keeps. Then it reads, from the
sentences of the cross-check report, the worst ratio of six classes and the case
where it occurred, and checks that our subset contains exactly that case with that
ratio: the hardest comparisons of the whole cross-check were made again here.
```

In [18]:

```
TABLE = {r["case"]: r for r in read_csv(f"{KS}/reports/ks-crosscheck-table.csv")}
matched, largest = 0, 0.0
for cls, case, *_, tolerance, diff, ratio in ROWS:

```

Text cell:

```
## 19. What this notebook showed

- The reference program, run again here on five states and on the fourth grid,
  reproduces the committed reference results: every number within one part in a
  billion (on the computer that built the book, byte for byte).
- Its grids converge like $h^2$: the differences shrink by a factor 4 from grid to
  grid, for $E_{KS}$ and for every level; two Richardson steps remove the $h^2$ and
  $h^4$ errors, and $U$ measures what is left. On a fourth grid every three-grid
  value of N136_lamp2_a20 moves by less than its $U$ (at most 0.787 of it, at the
  tip), so $U$ is a safe estimate of the remaining error.
- The Rust solver, run again with its canonical numerics, reproduces its committed
  results, and its refined run reproduces the recorded canonical-minus-refined
  differences, from which $U_{Rust} = \tfrac{16}{15}|canonical - refined|$.
- With the tolerance rule $|x_{Rust} - x_{ref}| \le 3(U_{ref} + U_{Rust}) +
  10^{-12}\,$scale, fixed before the comparison, all 5140 comparisons of the subset
  pass; our tolerances and ratios equal the 97 rows of the committed table, and the
```

```
  worst cases of six classes of the full cross-check (largest ratio 0.495) are
  reproduced exactly.
- What this does NOT show: both solvers implement the same functional, the same
  ASSUMED $Z_2$ brane, the same tip cutoff and the same filling CONVENTION, and both
  compute instantaneous (adiabatic) states along a PRESCRIBED BACKGROUND history. An
  error in those common inputs cannot be detected by comparing the two programs. The
  cross-check tests the numerics, not the physics model.
```

16.12 Line-by-line walk-through of Notebook 16a

The notebook has 23 code cells, In [1] to In [23]. This section explains every line of every one of them, in order. In the notebook each code cell is preceded by a text cell that says what the cell does; the numbers that the cells print are in Section 16.11 under the labels Out [k].

In [1], the set-up cell. It is the same in every notebook of the book except for the notebook's name and, in notebooks that run a Rust program, two more imports and the function `rust_program`; the walk-throughs of Notebooks 16b and 16c refer back to this paragraph. Its first 299 lines repeat the complete run instructions of Section 16.10 as **comment lines**: every line that starts with `#` is skipped by Python and is there only so that the notebook file carries its own instructions. Two lines of `=` signs around the title THE SET-UP mark where the code begins.

```
import json  # reads and writes JSON files (text files that hold names and numbers)
import os  # reads the environment variable TEXTBOOK_OUTPUT_ROOT (explained below)
import textwrap  # breaks long printed text into lines of at most 89 characters
from pathlib import Path  # file and folder paths that work on Windows, macOS and Linux

import matplotlib  # the plotting package
import matplotlib.pyplot as plt  # its drawing functions, called plt by convention
from IPython.display import Image, display  # shows a saved picture below a cell
import shutil  # finds the program cargo
import subprocess  # runs cargo and the Rust programs

NOTEBOOK_ID = "16a"  # this notebook: chapter 16, example a
```

`import` loads a **module** (a part of Python or of an installed package) so that the cell can use it; the text after `#` on each line says what the module is for. `json` reads and writes JSON files, the text format in which most Revision records are stored (names and numbers in braces). `os` gives access to the operating system, here to read an environment variable. `textwrap` breaks long printed text into lines. `from pathlib import Path` takes the single name `Path` out of the module `pathlib`; a `Path` is the address of a file or folder, written the same way on Windows, macOS and Linux. `matplotlib` is the plotting package, and `matplotlib.pyplot` its drawing functions, called `plt` by convention. `Image` and `display` show a saved picture below a cell. `shutil` can find a program on the computer (here cargo, the Rust build tool) and `subprocess` can run one. The last line gives the name `NOTEBOOK_ID` to the **string** (a text in quotes) `"16a"`; the figure files are named after it.

```
def find_repository_root():
    """Return the repository folder (Dirac_claude).

    Jupyter runs a notebook in the folder that holds it.  Starting there, go up one
```

```
    folder at a time until a folder contains Revision/textbook/requirements.txt (the
    list of the book's packages); that folder is the repository."""
    here = Path.cwd().resolve()  # the folder in which this notebook runs
    for folder in [here, *here.parents]:  # this folder, its parent, its grandparent ...
        if (folder / "Revision" / "textbook" / "requirements.txt").is_file():
            return folder
    raise FileNotFoundError(
        "The repository folder was not found: open this notebook inside the folder "
        "Revision/textbook/notebooks of the repository Dirac_claude")
```

`def` defines a **function**, a named piece of code that runs when it is called; the text in triple quotes under the `def` line is its **docstring**, a description that Python stores but does not run. `Path.cwd()` is the folder in which the notebook runs, and `.resolve()` writes it as a complete address. The list `[here, *here.parents]` holds this folder followed by its parent, the parent of that, and so on up to the top of the disk (the star unpacks the parents into the list); the `for` loop takes them one after the other. The operator `/` joins a folder and a name into a longer path, and `.is_file()` is true when that file exists. The first folder that holds `Revision/textbook/requirements.txt` is the repository, and `return` hands it back; if none does, `raise` stops the notebook with an error message that says what to do.

```
# The repository folder.  It is never printed: it differs from computer to computer,
# and the printed output of a notebook must not.
REPO = find_repository_root()
# Every file is WRITTEN below OUTPUT_ROOT.  OUTPUT_ROOT is the repository folder unless
# the environment variable TEXTBOOK_OUTPUT_ROOT names another folder; the book's
# checking tool sets it, so that a check run writes into a scratch folder instead.
OUTPUT_ROOT = Path(os.environ.get("TEXTBOOK_OUTPUT_ROOT", str(REPO)))

def repository_file(relative):
    """The path of the repository file relative, for READING (a Revision record)."""
    return REPO / relative

def output_file(relative):
    """The path at which to WRITE the repository file relative (its folder is made)."""
    path = OUTPUT_ROOT / relative
    path.parent.mkdir(parents=True, exist_ok=True)
    return path

def say(text):
    """Print text in lines of at most 89 characters (the width of a page of the book)."""
    print(textwrap.fill(str(text), width=89, subsequent_indent="    "))
```

`REPO` is the repository folder; it is never printed, because it differs from computer to computer while the printed output of the notebook must be the same everywhere. `os.environ.get(name, default)` reads an **environment variable** (a named text that a program receives from the computer) or returns the default; when you run the notebook the variable TEXTBOOK_OUTPUT_ROOT is not set, so `OUTPUT_ROOT` is the repository, while the book's checking tool sets it to a scratch folder so that a check never changes the repository. `repository_file` gives the full path of a repository file

for reading; `output_file` gives the full path at which to write one, after creating its folder (`mkdir` with `parents=True` creates missing parent folders too, and `exist_ok=True` makes it do nothing if the folder exists). `say` prints a text in lines of at most 89 characters (the width of a page of the book), continuation lines starting with four blanks.

```
matplotlib.rcdefaults()  # ignore personal matplotlib settings: same figures everywhere
plt.rcParams.update({"figure.figsize": (7.0, 4.2), "font.size": 10.0,
                     "axes.grid": True, "grid.alpha": 0.3})

FIGURE_FOLDER = "Revision/textbook/figures"  # where the figures are saved
CAPTION_FILE = f"{FIGURE_FOLDER}/{NOTEBOOK_ID}.captions.json"  # their captions
FIGURE_NUMBERS = {}  # figure name -> its number k (file name <id>_<k>_<name>.png)
CAPTIONS = {}  # figure file name -> caption, written to CAPTION_FILE after every figure
# Start with an empty captions file ({} is an empty JSON dictionary); save_figure fills
# it.  newline="\n" writes the same line ends on Windows, macOS and Linux.
output_file(CAPTION_FILE).write_text("{}\n", encoding="utf-8", newline="\n")
```

`matplotlib.rcdefaults()` returns to the built-in plotting settings, so that the figures are the same on every computer, and `plt.rcParams.update` sets the figure size (7.0 by 4.2 inches), the letter size (10 points) and a faint grid. The braces `{...}` make a **dictionary**: pairs of a key and a value, written `key:  value`. A string that starts with `f` is an **f-string**: every name in braces is replaced by its value, so `CAPTION_FILE` is `"Revision/textbook/figures/16a.captions.json"`. `FIGURE_NUMBERS` and `CAPTIONS` start as empty dictionaries. The last line writes an empty dictionary `{}` into the captions file; `newline="\n"` stores the same line end on every operating system.

```
def save_figure(fig, name, caption):
    """Save the figure fig as Revision/textbook/figures/<id>_<k>_<name>.png, record its
    caption in CAPTION_FILE, show the saved picture below the cell and close the figure.
    k counts the figures of the notebook 1, 2, 3, ...; a cell run again keeps its k."""
    number = FIGURE_NUMBERS.setdefault(name, len(FIGURE_NUMBERS) + 1)
    file_name = f"{NOTEBOOK_ID}_{number}_{name}.png"
    relative = f"{FIGURE_FOLDER}/{file_name}"
    # dpi=150: 150 dots per inch.  bbox_inches="tight": cut away the empty margin.
    # metadata={"Software": None}: no program name is stored in the PNG file, so that
    # every run writes exactly the same bytes.
    fig.savefig(output_file(relative), dpi=150, bbox_inches="tight",
                metadata={"Software": None})
    plt.close(fig)  # forget the figure, so that Jupyter does not draw it a second time
    CAPTIONS[file_name] = caption
    output_file(CAPTION_FILE).write_text(
        json.dumps(CAPTIONS, indent=1, sort_keys=True) + "\n", encoding="utf-8",
        newline="\n")
    display(Image(filename=str(output_file(relative))),
            metadata={"textbook_figure": file_name})  # the saved picture itself
    say(f"Figure {NOTEBOOK_ID}.{number} saved as {relative}")
```

`save_figure` numbers the figures 1, 2, 3, ... in the order in which they are saved (`setdefault` returns the number already stored for this name, or stores one more than the count so far), saves the figure as a PNG file with 150 dots per inch, cut to its content and without the program's name in the file (so that two runs write the same bytes), closes it, records its caption in the captions file

(`json.dumps` turns the dictionary into JSON text, with one entry per line and the keys sorted), shows the saved picture below the cell, and prints where it was saved. The caption given to it is the caption that the book prints under the figure.

```
PASSED = []  # the names of the checks that passed, in order

def check(condition, name, record=None):
    """A check.  If condition is False, stop with an AssertionError that names the
    check (an if statement is used instead of assert, because python -O would skip an
    assert).  Otherwise print "PASS <name>" and, when the check reproduces a Revision
    record, a second line naming the record file and its check."""
    if not condition:
        raise AssertionError(f"check failed: {name}")
    PASSED.append(name)
    say(f"PASS {name}")
    if record is not None:
        say(f"     reproduces {record}")

def report(label, value, unit=""):
    """Print a key number as a line "RESULT <label> = <value> <unit>"."""
    say(f"RESULT {label} = {value}" + (f" {unit}" if unit else ""))

def all_checks_passed():
    """Print the last line of the notebook: how many checks passed."""
    print(f"ALL {len(PASSED)} CHECKS PASSED (notebook {NOTEBOOK_ID})")
```

`PASSED` is an empty **list** (an ordered collection, in square brackets). `check` is the function behind every check of the notebook: if the statement `condition` is false, `raise AssertionError(...)` stops the notebook with an error that names the check; if it is true, the name is appended to `PASSED` and the line PASS followed by the name is printed, and a second line names the Revision record and its check when the argument `record` is given (`None` is Python's word for "nothing"). Python's own `assert` statement is not used, because Python started with the option `-O` skips it. `report` prints a key number as a line that starts with RESULT. `all_checks_passed` prints the last line of the notebook with the number of checks that passed; `len` is the length of a list.

```
def rust_program(manifest, binary):
    """Build the Rust program binary of the crate whose Cargo.toml is manifest (a
    repository path) with "cargo build --release" (about a second when it is up to date;
    minutes the first time) and return the path of the program."""
    if shutil.which("cargo") is None:
        raise FileNotFoundError(
            "cargo was not found: install Rust from https://rustup.rs, open a new "
            "terminal, activate the environment and start JupyterLab again")
    crate = (REPO / manifest).parent  # the folder that holds Cargo.toml
    completed = subprocess.run(
        ["cargo", "build", "--release", "--manifest-path", str(REPO / manifest),
         "--target-dir", str(crate / "target")],
        capture_output=True, text=True, encoding="utf-8", errors="replace")
```

```
    if completed.returncode != 0:  # show the end of cargo's error message
        print(completed.stderr[-3000:])
        raise RuntimeError(f"cargo build failed for {manifest}")
    for file_name in (binary, binary + ".exe"):  # Linux and macOS; Windows
        path = crate / "target" / "release" / file_name
        if path.is_file():
            say(f"Rust program {binary} is built and ready.")
            return path
    raise FileNotFoundError(f"cargo built {manifest} but {binary} is missing")
```

`rust_program` builds a Rust program and returns where it is. `shutil.which("cargo")` looks for the program cargo; if it is not found (`is None`), the function stops with a message that says how to install Rust. `crate` is the folder that holds the file `Cargo.toml` (`.parent` removes the last part of a path). `subprocess.run([...])` runs cargo with the arguments in the list, exactly as if the release build command for this manifest were typed into a terminal; `capture_output=True` keeps cargo's messages instead of printing them, and `text=True` with `encoding="utf-8"` reads them as text. The **return code** of a program is 0 when it succeeded; otherwise the function prints the last 3000 characters of cargo's error messages (`[-3000:]` takes the end of a string) and stops. The `for` loop tries the program's name without and with the ending `.exe` (Linux and macOS have no ending, Windows has `.exe`) and returns the first one that exists, after printing that the program is ready.

```
say(f"Set-up of notebook {NOTEBOOK_ID} complete: repository folder found, helpers "
    "defined.")
```

The last statement prints the one output line of In [1].

In [2], the records and the problem definition of both solvers.

```
import csv  # reads tables stored as CSV files (comma-separated values)
import re  # finds patterns in text (used to read numbers out of report sentences)
import sys  # the list of folders in which Python looks for modules
import tempfile  # makes temporary folders outside the repository

import numpy as np  # arrays of numbers

KS = "Revision/kohn_sham"  # the folder of the Kohn-Sham record (repository path)
PALETTE = ["#2a78d6", "#eb6834", "#1baf7a", "#eda100", "#e87ba4", "#008300",
           "#4a3aa7", "#e34948"]  # the colours of the figures, in a fixed order
```

Four more modules: `csv` reads tables stored as CSV files (comma-separated values: one line per row, the entries separated by commas), `re` finds patterns in text (**regular expressions**, used below to read numbers out of the sentences of a report), `sys` gives access to the list of folders in which Python looks for modules, and `tempfile` makes temporary folders in the place the operating system keeps for temporary files, outside the repository (In [12] uses it for the raw outputs of the Rust runs). `numpy`, called `np`, holds arrays of numbers. `KS` is the folder of the Kohn-Sham record, and `PALETTE` a list of eight colours, written as hexadecimal codes, used in a fixed order by all figures.

```
def read_json(relative):
    """Read a JSON file of the repository (a Revision record)."""
```

```
    return json.loads(repository_file(relative).read_text(encoding="utf-8"))

def read_csv(relative):
    """Read a CSV file of the repository: a list of rows, each row a dictionary from
    the column names to the texts in that row."""
    with open(repository_file(relative), newline="", encoding="utf-8") as handle:
        return list(csv.DictReader(handle))
```

Two small reading functions. `read_json` reads a repository file as text and turns it into Python objects with `json.loads` (dictionaries, lists, numbers and strings). `read_csv` opens a CSV file (`with open(...) as handle:` opens it and closes it again when the indented block ends), and `csv.DictReader` reads it row by row, each row a dictionary from the column names of the first line to the texts in that row; `list(...)` collects all rows.

```
REPORTS = {"reference solver": read_json(f"{KS}/reports/ks-reference.json"),
           "Rust solver": read_json(f"{KS}/reports/ks-rust-solver.json"),
           "cross-check": read_json(f"{KS}/reports/ks-crosscheck.json")}
counts = {}
for label, rep in REPORTS.items():
    summary = rep["summary"]  # {"checks": ..., "pass": ..., "fail": ...}
    counts[label] = (summary["pass"], summary["checks"])
    say(f"{label}: {summary['pass']} of {summary['checks']} checks PASS")
check(counts == {"reference solver": (37, 37), "Rust solver": (42, 42),
                 "cross-check": (31, 31)},
      "the three committed reports pass every check (37, 42 and 31)")
CROSS = {c["name"]: c for c in REPORTS["cross-check"]["checks"]}  # name -> check
for name in ["thermo_levels", "thermo_mu_rust_stated_bound"]:  # the two newest
    detail = CROSS[name]["detail"]  # the report's sentence about this check
    size = re.search(r"(\d+) comparisons", detail).group(1)  # a number in the text
    say(f"cross-check {name}: {size} comparisons, verdict {CROSS[name]['verdict']}")
```

`REPORTS` is a dictionary of the three committed reports: the reference solver's self-checks, the Rust solver's self-checks, and the cross-check. The loop goes through its pairs (`.items()`); each report has an entry `summary` with the numbers of checks and of PASS verdicts, which the loop stores in `counts` as a **tuple** (an unchangeable pair in round brackets) and prints. The check requires exactly 37 of 37, 42 of 42 and 31 of 31; Out [2] shows the three lines and the PASS line. `CROSS` is a dictionary from the name of each check of the cross-check to the check itself, which is again a dictionary with three entries: `name`, `verdict` (PASS or FAIL) and `detail`, the sentence in which the report describes what was compared and what was found (the `{... for c in ...}` form builds a dictionary in one line, as a list comprehension builds a list). The loop takes the two checks that were added to the cross-check on 2026-10-08 (Section 16.8). For each, `detail` is its sentence, and `re.search` looks in it for the pattern `(\d+) comparisons`: `\d` stands for any digit, `+` for one or more of them, and the round brackets mark the part to keep, which `.group(1)` returns (the `r` before the quotes keeps the backslash as it is). The two printed lines give 34378 and 270 comparisons and the verdict that the report records for each check, PASS; this agrees with the check above, which found 31 PASS verdicts among 31 checks. These two lines are printed information, not checks of the notebook: they do not count among its 51 checks.

```
RUST_PARAMS = read_json(f"{KS}/results/parameters.json")  # the Rust solver's
REF_PARAMS = read_json(f"{KS}/reference/results/parameters.json")  # the reference's
```

```
pairs = [("H", "H"), ("m", "m"), ("L_tipCutoff", "L"), ("dk", "dk"), ("v_t", "vt"),
         ("tipTheta", "tipTheta"), ("historyA", "historyA"),
         ("slicesA4", "slicesA4"), ("temperatures", "temperatures")]
differ = [rust_name for rust_name, ref_name in pairs
          if RUST_PARAMS["physics"][rust_name] != REF_PARAMS["physics"][ref_name]]
same_theory = (RUST_PARAMS["theoryInputs"]["ksTheorySha256"]
               == REF_PARAMS["theoryInputs"]["ksTheorySha256"])
for rust_name, ref_name in pairs:
    say(f"  {rust_name:13s} Rust {RUST_PARAMS['physics'][rust_name]}   reference "
        f"{REF_PARAMS['physics'][ref_name]}")
check(not differ and same_theory,
      "both solvers solve the same problem and read the same ks-theory.json",
      record=f"{KS}/reports/ks-crosscheck.json, check problem_definition_identical")
```

`RUST_PARAMS` and `REF_PARAMS` are the `parameters.json` files of the two solvers. The two programs name some constants differently (the tip cutoff is `L_tipCutoff` in one and `L` in the other), so `pairs` lists the names side by side. `differ` is built by a **list comprehension**, `[expression for ... in ... if condition]`, which collects the Rust name of every pair whose two values are not equal (`!=`); it must be empty. `same_theory` compares the SHA-256 fingerprints (a 64-character number computed from every byte of a file; two different files practically never have the same one) of the theory file that each solver read. The loop prints the nine pairs of values, the name padded to 13 characters (`:13s`). The check requires no difference and the same theory file, and names the cross-check's check `problem_definition_identical`, which it reproduces.

```
LAMBDAS = {}  # N -> {"lamp1": +lambda_1, ...}: the couplings of the reference
rust_cal = {c["N"]: c for c in RUST_PARAMS["couplingCalibration"]["values"]}
same_couplings = True
for cal in REF_PARAMS["derived"]["calibration"]:
    N = cal["N"]
    LAMBDAS[N] = {"lam0": 0.0, "lamp1": cal["lambda1"], "lamm1": -cal["lambda1"],
                  "lamp2": cal["lambda2"], "lamm2": -cal["lambda2"]}
    same_couplings &= (cal["lambda1"] == rust_cal[N]["lambda1"]
                       and cal["lambda2"] == rust_cal[N]["lambda2"])
    say(f"N = {N:5.0f}: lambda_1 = {cal['lambda1']}, lambda_2 = {cal['lambda2']}")
check(same_couplings, "the six couplings derived by the two solvers are identical",
      record=f"{KS}/reports/ks-crosscheck.json, check parameters_couplings")
```

Each solver derived the couplings λ_1 and λ_2 for each particle number on its own, from the same rule (Section 16.3). `rust_cal` is a **dictionary comprehension** that files the Rust values under their N. The loop goes through the reference's values, stores for each N the five couplings of the tags lam0, lamp1, lamm1, lamp2, lamm2 in `LAMBDAS` (they are used by the next cells), and compares with the Rust values; `same_couplings &= ...` keeps `same_couplings` true only while every comparison is true (`&=` combines with "and"). `{N:5.0f}` prints N in five places without decimals. Out [2] shows $\lambda_1 = 0.01946$, $\lambda_2 = 0.05838$ for $N = 8$, 0.0009298 and 0.002789 for $N = 136$, and 0.0001846 and 0.0005538 for $N = 688$, identical in both solvers.

In [3], the reference program and the five states.

```
sys.dont_write_bytecode = True  # do not write a __pycache__ folder into the record
sys.path.insert(0, str(repository_file(f"{KS}/reference")))  # Python looks here too
```

```
import run_reference as RR  # noqa: E402  the reference program (Revision code)

CO = RR.theory_coefficients()  # coefficients read and checked from ks-theory.json
say(f"functional coefficients: M_eff = m + {CO['cM']} lambda S, "
    f"v_v = {CO['cV']} lambda n, e_int = lambda ({CO['eS2']} S^2 + {CO['eN2']} n^2)")
```

`sys.dont_write_bytecode = True` stops Python from writing a folder of translated files (`__pycache__`) next to the imported program, which would otherwise appear inside the Revision record. `sys.path.insert(0, ...)` puts the folder of the reference program at the front of the list of folders in which Python looks for modules, so that `import run_reference as RR` finds `Revision/kohn_sham/reference/run_reference.py` and makes it available under the short name `RR`. Importing does not run the program: its last lines start the computation only when it is run as a program, so the import only defines its functions. (The comment `noqa: E402` tells a style checker that an import in the middle of a cell is intended.) `RR.theory_coefficients()` reads the coefficients of the functional from `ks-theory.json` as exact fractions; the printed line, Out [3], shows $M_{eff} = m + \frac{15}{16}\lambda S$, $v_v = -\frac{1}{16}\lambda n$ and $e_{int} = \lambda(\frac{15}{32}S^2 - \frac{1}{32}n^2)$, the formulas of Chapter 14.

```
def job_spec(N, tag, a4, T=None):
    """The reference program's description of one state (a dictionary)."""
    spec = {"id": RR.run_id(N, tag, a4, T), "N": N, "tag": tag,
            "lam": LAMBDAS[N][tag], "a4": a4, "sigma": RR.SIGMA[tag]}
    if T is not None:
        spec["T"] = T
    return spec
```

`job_spec` writes one state as the reference program describes it: a dictionary with the id (made by the program's own function `RR.run_id`, so that the names agree with the record's file names), N, the coupling tag and its value from `LAMBDAS`, the slice, the first-order mean-field size σ of the tag (`RR.SIGMA`: 0 for lam0, 0.1 for $\pm\lambda_1$, 0.3 for $\pm\lambda_2$; it decides how many levels the label set keeps), and, for a thermal state, the temperature. `T=None` makes the temperature optional.

```
SPECS = {}
for args in [(8.0, "lamm2", 0.0), (688.0, "lam0", 0.0), (136.0, "lamp2", 2.0),
             (8.0, "lamm1", 0.0, 0.01), (8.0, "lam0", 1.5, 0.05)]:
    spec = job_spec(*args)
    SPECS[spec["id"]] = spec
GROUND_IDS = ["N8_lamm2_a00", "N688_lam0_a00", "N136_lamp2_a20"]
THERMAL_IDS = ["N8_lamm1_a00_T10", "N8_lam0_a15_T50"]
print("state               N   lambda       a4,0  sigma  T")
for sid, spec in SPECS.items():
    print(f"{sid:18s} {spec['N']:4.0f}  {spec['lam']:+.5f}  {spec['a4']:4.1f}  "
          f"{spec['sigma']:4.1f}   {spec.get('T', 0.0):.2f}")
check(sorted(SPECS) == sorted(GROUND_IDS + THERMAL_IDS),
      "the five job descriptions have the ids of the subset")
```

The loop makes the five job descriptions; `job_spec(*args)` unpacks each tuple into the arguments of the function, and the descriptions are filed under their ids in `SPECS`. `GROUND_IDS` and `THERMAL_IDS` list the five ids in the order used below. The table printed by the loop (Out [3]) shows each state's N, coupling (with sign and five decimals, `:+.5f`), slice, σ and temperature (`spec.get("T",`

0.0) gives 0 when a state has no temperature). The check compares the sorted ids with the five ids of the subset.

In [4], the reference solver on the three ground states.

```
PER_GRID = {}  # (state id, G) -> the levels of the state on grid G (an array)
original_ground_on_grid = RR._ground_on_grid  # the reference's function for one grid

def ground_on_grid_recorded(co, spec, G, labels):
    """Call the reference's own function for one grid and keep a copy of its levels."""
    result = original_ground_on_grid(co, spec, G, labels)
    PER_GRID[(spec["id"], G)] = result["eps"].copy()
    return result
```

The reference's ground-state job calls the program's internal function `_ground_on_grid` once per grid and keeps only the extrapolated levels. To draw the convergence of every level (In [10]) we want the levels on each grid as well. `original_ground_on_grid` keeps the program's function under a second name. The new function `ground_on_grid_recorded` takes the same four arguments, calls the original function, stores a copy of the levels it returned (`result["eps"]`, a numpy array; `.copy()` makes an independent copy) in `PER_GRID` under the pair (state id, grid), and passes the result on unchanged. Such a function, which calls another and adds something around it, is called a **wrapper**.

```
RR._ground_on_grid = ground_on_grid_recorded  # the job now calls our wrapper
NEW = {}  # state id -> the new reference result (the content of its JSON file)
for sid in GROUND_IDS:
    NEW[sid] = RR.jsonable(RR.ground_job(CO, SPECS[sid])["data"])
    E = NEW[sid]["scalars"]["E_KS"]
    say(f"{sid}: {NEW[sid]['levels_in_set']} levels, E_KS = {E['value']:.13f} "
        f"(U = {E['U']:.1e})")
RR._ground_on_grid = original_ground_on_grid  # put the original function back
check(len(PER_GRID) == 9, "the levels of three states on three grids were kept")
```

`RR._ground_on_grid = ground_on_grid_recorded` puts the wrapper in the place of the program's function: the job looks the function up by its name in its module each time, so from now on it calls the wrapper. The loop runs the job `RR.ground_job` for each ground state; its result is a dictionary whose entry `data` is the content of the JSON file that the program writes, and `RR.jsonable` turns its numpy arrays into plain Python numbers exactly as the program does before writing. Each line of Out [4] prints the number of levels kept and the Richardson value of E_{KS} with its uncertainty: N8_lamm2_a00 has 22 levels and $E_{KS} = 0.0028626521737$ ($U = 2.1 \times 10^{-12}$), N688_lam0_a00 has 137 levels and $E_{KS} = 680.4412465815219$ ($U = 3.3 \times 10^{-9}$), N136_lamp2_a20 has 354 levels and $E_{KS} = 12.4489994812532$ ($U = 4.6 \times 10^{-11}$). Then the original function is put back, and the check confirms that nine level arrays (three states, three grids) were kept. This cell runs for one to three minutes on a fast computer: N136_lamp2_a20 alone solves 354 levels on three grids, each with its excited state and four neighbouring slices.

In [5], comparing the new results with the committed files.

```
def compare_records(new, old, problems, where="top"):
    """Compare two JSON structures; return the number of numbers compared and append
```

```
    a description of every difference to the list problems."""
    if isinstance(new, bool) or isinstance(old, bool) or new is None or \
            isinstance(new, str):
        if new != old:
            problems.append(f"{where}: {new!r} != {old!r}")
        return 0
    if isinstance(new, (int, float)):
        if not isinstance(old, (int, float)) or \
                abs(new - old) > 1e-9 * max(1.0, abs(old)):
            problems.append(f"{where}: {new!r} != {old!r}")
        return 1
```

`compare_records` walks through two JSON structures at the same time and counts the numbers it compared. This first part handles the simplest cases. `isinstance(x, bool)` asks whether `x` is a truth value; a truth value, a missing value (`None`) or a text must be equal, and every inequality is appended to the list `problems` as a line naming the place (`{new!r}` writes the value as Python would type it). A number (`int` or `float`) must be within one part in a billion of the committed one, measured relative to $\max(1, |old|)$; it counts as one compared number. (A backslash at the end of a line continues the statement on the next line.)

```
    if isinstance(new, dict):
        if sorted(new) != sorted(old):
            problems.append(f"{where}: different names")
            return 0
        return sum(compare_records(new[k], old[k], problems, f"{where}/{k}")
                   for k in new)
    if len(new) != len(old):  # a list
        problems.append(f"{where}: lengths {len(new)} and {len(old)}")
        return 0
    return sum(compare_records(a, b, problems, f"{where}[{i}]")
               for i, (a, b) in enumerate(zip(new, old)))
```

For a dictionary both must have the same names (sorted, because the order does not matter); then the function calls itself for each entry, with the place extended by `/name`, and adds up the counts with `sum(...)`. A function that calls itself is **recursive**: it goes down into the nested structure until it reaches single values. Anything else is a list: both must have the same length, and the function compares them entry by entry (`zip` pairs the entries, `enumerate` numbers them, and the place is extended by `[i]`).

```
def check_reproduction(label, data, relative):
    """Check the new result data (named label) against its committed file."""
    committed = repository_file(relative).read_text(encoding="utf-8")
    problems = []
    numbers = compare_records(data, json.loads(committed), problems)
    text = json.dumps(data, indent=1, ensure_ascii=True) + "\n"  # as written
    say(f"{label}: {numbers} numbers compared; identical byte for byte: "
        f"{text == committed}")
    for line in problems[:5]:  # the first differences, if there are any
        say(f"  difference {line}")
    check(not problems,
```

```
        f"the re-run of {label} reproduces {relative.split('/results/')[1]}",
        record=f"{KS}/reports/ks-crosscheck.json, check "
               "reference_repeat_byte_identical")
```

`check_reproduction` reads the committed file as text, compares its content with the new result, and also writes the new result as text exactly as the reference program writes its files (`json.dumps` with an indentation of one blank and only ASCII characters, plus a final line end) to report whether the two texts are identical byte for byte. It prints the number of numbers compared and that answer, then the first five differences, if any (`problems[:5]` is the first five entries of a list). The check requires no difference; its name gives the file name after `/results/` (`.split('/results/')[1]` cuts the path at that text and takes the second piece), and its record line names the cross-check's check `reference_repeat_byte_identical`, which made the same test for all files.

```
for sid in GROUND_IDS:
    check_reproduction(sid, NEW[sid], f"{KS}/reference/results/ground/{sid}.json")
```

The loop applies this to the three ground states. Out [5] shows 3597, 4513 and 5815 numbers compared, every file identical byte for byte, and three PASS lines.

In [6], Richardson extrapolation at work.

```
def richardson(x1, x2, x3):
    """Three-grid Richardson value R and its uncertainty U (x1 on the coarsest grid),
    in the two-step form of the reference program; also the two one-step values."""
    r_fine = (4.0 * x3 - x2) / 3.0  # one step on the grids h/2 and h/4
    r_coarse = (4.0 * x2 - x1) / 3.0  # one step on the grids h and h/2
    R = (16.0 * r_fine - r_coarse) / 15.0  # the second step
    U = abs(R - r_fine) + 2e-12 * max(1.0, abs(R))
    return R, U, r_coarse, r_fine
```

`richardson` is the two-step extrapolation of Section 16.5 written in Python: `r_fine` is the one-step value $r(h/2)$ of the two finer grids, `r_coarse` the one-step value $r(h)$, `R` the second step $(16\,r(h/2) - r(h))/15$, and `U` the uncertainty $|R - r(h/2)| + 2 \cdot 10^{-12} \max(1, |R|)$. The function returns all four numbers.

```
CONVERGENCE = {}  # state id -> (E_KS on the three grids, R)
for sid in GROUND_IDS:
    xs = [grid["scalars"]["E_KS"] for grid in NEW[sid]["per_grid"]]
    R, U, _, _ = richardson(*xs)
    R_one_line = (64.0 * xs[2] - 20.0 * xs[1] + xs[0]) / 45.0
    stored = NEW[sid]["scalars"]["E_KS"]
    ratio = (xs[0] - xs[1]) / (xs[1] - xs[2])
    CONVERGENCE[sid] = (xs, R)
    say(f"{sid}: E_KS(300) = {xs[0]:.12f}, E_KS(600) = {xs[1]:.12f}, "
        f"E_KS(1200) = {xs[2]:.12f}")
    say(f"    R = {R:.13f}, U = {U:.1e}, ratio of the differences = {ratio:.5f}")
    check(abs(R - stored["value"]) <= 1e-14 * max(1.0, abs(R))
          and abs(U - stored["U"]) <= 1e-14 * max(1.0, abs(R))
          and abs(R_one_line - R) <= 1e-13 * max(1.0, abs(R)),
          f"our Richardson lines give the reference value and U of E_KS ({sid})")
```

For each ground state the list comprehension takes E_{KS} from the three per-grid records of the new result (`per_grid` holds one record per grid, coarsest first). `R, U, _, _ = richardson(*xs)` keeps the first two returned numbers (the underscore is a name for values that are not needed). `R_one_line` is the one-line form $(64x(h/4) - 20x(h/2) + x(h))/45$ of Section 16.5, `stored` the value and uncertainty that the reference program wrote, and `ratio` the convergence ratio of Section 16.4. The three values are kept in `CONVERGENCE` for the figure of In [8]. The two printed lines per state (Out [6]) show the three grid values, R, U and the ratio: 4.00020, 4.00007 and 4.00006. The check requires our R and U to equal the program's within 10^{-14} (relative) and the two written forms of R to agree within 10^{-13}: Section 16.5's algebra and the program agree.

In [7], a fourth grid tests the uncertainty.

```
FOUR_GRIDS = {}  # G -> (E_KS, levels, p0 at the tip) of N136_lamp2_a20 on grid G
original_observables = RR.K.observables  # the function of ks_fd (RR.K is ks_fd)

def observables_recorded(state):
    """Call ks_fd's own function and keep E_KS, the levels and p0 at the tip."""
    scalars, profiles = original_observables(state)
    FOUR_GRIDS[state.grid.G] = (scalars["E_KS"], state.eps.copy(),
                                scalars["p0_tip"])
    return scalars, profiles
```

A second wrapper, for the function `observables` of the module `ks_fd` (the reference program imported this module under the name `K`, so it is `RR.K` here). The validation job calls it once on each of the four grids; the wrapper keeps the grid's E_{KS}, a copy of its levels and the value of p_0 at the tip in `FOUR_GRIDS`, under the number of cells `state.grid.G`.

```
RR.K.observables = observables_recorded  # the job now calls our wrapper
VALIDATION = RR.jsonable(RR.validation_job(CO, SPECS["N136_lamp2_a20"])["data"])
RR.K.observables = original_observables  # put the original function back
check_reproduction("the fourth-grid validation", VALIDATION,
                   f"{KS}/reference/results/validation/N136_lamp2_a20.json")
same = all(abs(FOUR_GRIDS[G][0] - grid["scalars"]["E_KS"]) <= 1e-12
           for G, grid in zip((300, 600, 1200), NEW["N136_lamp2_a20"]["per_grid"]))
check(sorted(FOUR_GRIDS) == [300, 600, 1200, 2400] and same,
      "the validation run repeats the ground job's E_KS on the three common grids")
```

The wrapper is put in place, the program's job `RR.validation_job` solves N136_lamp2_a20 on $G = 300$, 600, 1200 and 2400 (about 40 seconds), and the original function is put back. `check_reproduction` compares the result with the committed file `validation/N136_lamp2_a20.json` (Out [7]: 99 numbers, identical byte for byte). The second check confirms that the validation run repeats the ground job's E_{KS} on the three common grids to 10^{-12} (`all(...)` is true when every comparison in the brackets is true) and that the four grids were recorded.

```
classes = VALIDATION["classes"]
for name, c in classes.items():
    say(f"  {name:20s} {c['elements']:4d} element(s): max |R123 - R234| / U123 = "
        f"{c['max_ratio_to_U123']:.2e}")
```

```
worst = max(classes, key=lambda name: classes[name]["max_ratio_to_U123"])
detail = next(c["detail"] for c in REPORTS["reference solver"]["checks"]
              if c["name"] == "richardson_uncertainty_validated")
stated = float(re.search(r"U123 = ([0-9.]+) \((\w+)\)", detail).group(1))
say(f"largest ratio {classes[worst]['max_ratio_to_U123']:.3f} ({worst}); "
    f"the report states {stated}")
check(all(c["all_within_U123"] for c in classes.values())
      and len(classes) == 19 and worst == "p0_tip"
      and abs(classes[worst]["max_ratio_to_U123"] - stated) <= 5e-4,
      "on the fourth grid every three-grid value moves by less than its U",
      record=f"{KS}/reports/ks-reference.json, check richardson_uncertainty_validated")
```

`classes` holds the 19 quantity classes of the validation, each with its number of elements and the largest ratio $|R_{123} - R_{234}|/U_{123}$; the loop prints them (Out [7]: from 0 for the integral of p_3 to 0.787 for p_0 at the tip). `max(classes, key=...)` finds the class with the largest ratio: the `key` is a **lambda**, a one-line function written in place, that gives each class name its ratio. `next(... for c in ... if ...)` takes the first check of the reference report whose name is `richardson_uncertainty_validated`, and `re.search` reads the number after the text `U123 =` in its detail sentence: in the pattern, `[0-9.]+` means one or more digits or points, round brackets capture what they match (`.group(1)` returns it), `\(` and `\)` are literal brackets, and `\w+` is a word. The check requires every element of every class to lie within its U_{123}, 19 classes, the largest ratio at `p0_tip`, and our largest ratio equal to the one stated in the report within 5×10^{-4}.

In [8], convergence as a picture (Figure 16a.1).

```
fig, (left, right) = plt.subplots(1, 2, figsize=(10.0, 4.3))
h = np.array([3.0 / 300, 3.0 / 600, 3.0 / 1200])  # the cell widths
for colour, sid in zip(PALETTE, GROUND_IDS):
    xs, R = CONVERGENCE[sid]
    left.loglog(h, [abs(x - R) for x in xs], "o-", color=colour, lw=1.5, ms=6,
                label=sid)
    first = abs(xs[0] - R)  # a guide of slope 2, a factor 3 below the first point
    left.loglog(h, first / 3.0 * (h / h[0]) ** 2, "--", color=colour, lw=0.9)
left.set_xlabel("cell width $h = L/G$")
left.set_ylabel("$|E_{KS}(G) - R|$ (units of $m$)")
left.set_title("three grids, three states")
left.legend(fontsize=8)
```

`plt.subplots(1, 2, ...)` makes a figure with two sets of axes side by side, `left` and `right`, 10 by 4.3 inches. `h` is the numpy array of the three cell widths 3/300, 3/600, 3/1200. For each ground state (`zip` pairs the colours with the ids) the left axes draw the distances $|E_{KS}(G) - R|$ against h with **logarithmic axes** (`loglog`: equal distances on the axis are equal factors), as circles joined by lines (`"o-"`, line width 1.5, marker size 6), and a dashed **guide line** proportional to h^2 that starts a factor 3 below the first point. On logarithmic axes a power law Ch^q is a straight line of slope q, so points parallel to the guide show an error proportional to h^2. The labels, title and legend complete the panel.

```
grids = [300, 600, 1200, 2400]
e4 = [FOUR_GRIDS[G][0] for G in grids]  # E_KS of N136_lamp2_a20 on the four grids
h4 = np.array([3.0 / G for G in grids])
```

```
R123, U123, _, _ = richardson(*e4[:3])
R234, _, _, _ = richardson(*e4[1:])
single = [abs(x - R234) for x in e4]
one_step = [abs((4.0 * e4[i + 1] - e4[i]) / 3.0 - R234) for i in range(3)]
```

For the right panel: `e4` is E_{KS} of N136_lamp2_a20 on the four grids (kept by the wrapper of In [7]), `h4` their cell widths, `R123` and `U123` the three-grid value and uncertainty of the three coarser grids (`e4[:3]` is the first three entries), and `R234` the three-grid value of the three finer ones (`e4[1:]` is everything after the first). `single` holds the distance of each single-grid value from R_{234}, and `one_step` the distance of each one-step value $(4x(2G) - x(G))/3$ from it.

```
right.loglog(h4, single, "o-", color=PALETTE[0], lw=1.5, ms=6,
             label="single grid $x(G)$")
right.loglog(h4, single[0] / 3.0 * (h4 / h4[0]) ** 2, "--", color=PALETTE[0],
             lw=0.9, label="slope 2 (shifted down)")
right.loglog(h4[:3], one_step, "s-", color=PALETTE[1], lw=1.5, ms=6,
             label="one step $r$ (pair $G$, $2G$)")
right.loglog(h4[:3], one_step[0] / 3.0 * (h4[:3] / h4[0]) ** 4, "--",
             color=PALETTE[1], lw=0.9, label="slope 4 (shifted down)")
right.loglog([h4[0]], [max(abs(R123 - R234), 1e-16)], "D", color=PALETTE[2], ms=8,
             label="three grids $R_{123}$")
right.loglog([h4[0]], [U123], "_", color="k", ms=16, mew=2,
             label="its uncertainty $U_{123}$")
right.set_xlabel("cell width $h$ of the coarsest grid used")
right.set_ylabel("distance from $R_{234}$ (units of $m$)")
right.set_title("N136_lamp2_a20 on four grids")
right.legend(fontsize=7, loc="center right")
```

The right panel draws the single-grid distances with a dashed slope-2 guide, the one-step distances (squares) with a dashed slope-4 guide (h^4 is the error of a one-step value, Section 16.5), the distance $|R_{123} - R_{234}|$ as a diamond (`max(..., 1e-16)` keeps a zero away from the logarithmic axis) and the uncertainty U_{123} as a short horizontal bar (marker `"_"`, black, edge width 2).

```
for ax, ticks in ((left, h), (right, h4)):  # tick labels at the grids' h only
    ax.xaxis.set_minor_formatter(matplotlib.ticker.NullFormatter())
    ax.set_xticks(ticks)
    ax.set_xticklabels([f"{t:g}" for t in ticks])
fig.tight_layout()
```

For both panels the tick labels are set at the grids' cell widths only: `NullFormatter` removes the labels of the small in-between ticks, `set_xticks` puts ticks at the given values, and `set_xticklabels` writes them in the shortest form (`:g`). `fig.tight_layout()` arranges the panels so that their labels do not overlap.

```
save_figure(fig, "grid_convergence",
            "Convergence of the reference solver for the Kohn-Sham energy $E_{KS}$, "
            "logarithmic axes, energies in units of the mass $m$. Left: distance of "
            "the single-grid value from the Richardson value $R$ against the cell "
            "width $h = 3/G$ for $G = 300, 600, 1200$ for the three ground states; "
```

```
            "the points run parallel to the dashed lines of slope 2 (drawn a factor 3 "
            "lower), an error proportional to $h^2$. Right: the state N136_lamp2_a20 "
            "also on $G = 2400$, every "
            "distance measured from the four-grid best value $R_{234}$: single grids "
            "fall with slope 2, one Richardson step with slope 4, and the three-grid "
            "value $R_{123}$ (diamond) lies far below its stated uncertainty "
            "$U_{123}$ (bar), so $U$ is a safe over-estimate.")
check(all(abs(CONVERGENCE[s][0][0] - CONVERGENCE[s][1])
          > abs(CONVERGENCE[s][0][2] - CONVERGENCE[s][1]) for s in GROUND_IDS)
      and single[0] > single[1] > single[2] > single[3]
      and one_step[0] > one_step[1] > one_step[2] and abs(R123 - R234) <= U123,
      "the errors shrink grid by grid and R123 lies within U123 of R234")
```

`save_figure` saves Figure 16a.1 with its caption (Python joins strings written next to each other into one). What the student should see: on the left, three straight lines parallel to their slope-2 guides, the errors of the three states falling by a factor 4 from grid to grid although their sizes differ by five powers of ten; on the right, the slope-2 line of the single grids, the slope-4 line of one Richardson step, and the diamond of R_{123}, only 3.6×10^{-14} from R_{234} (`Revision/kohn_sham/reference/results/validation/N136_lamp2_a20.json`, class E_KS), far below the bar of its uncertainty $U_{123} = 4.6 \times 10^{-11}$: the uncertainty is a safe over-estimate. The check confirms what the picture shows: for each state the error shrinks from the coarsest to the finest grid, the single-grid and one-step distances shrink monotonically, and R_{123} lies within U_{123} of R_{234}.

In [9], the fourth-grid test as a bar chart (Figure 16a.2).

```
names = list(classes)  # the 19 classes in the order of the record
values = [max(classes[n]["max_ratio_to_U123"], 1e-8) for n in names]
fig, ax = plt.subplots(figsize=(7.5, 6.2))
colours = [PALETTE[1] if n == worst else PALETTE[0] for n in names]
ax.barh(range(len(names)), values, color=colours, height=0.65)
ax.set_xscale("log")
ax.axvline(1.0, color="k", lw=1.2)
ax.set_yticks(range(len(names)))
ax.set_yticklabels([f"{n} ({classes[n]['elements']})" for n in names], fontsize=8)
ax.invert_yaxis()  # the first class at the top
ax.set_xlim(1e-9, 3.0)
```

`names` is the list of the 19 class names in the order of the record, and `values` their largest ratios, with exact zeros raised to 10^{-8} so that they can be drawn on a logarithmic axis. `colours` marks the worst class in orange (the second palette colour) and the others in blue. `barh` draws horizontal bars, one per class, at the heights 0 to 18; `set_xscale("log")` makes the horizontal axis logarithmic; `axvline(1.0, ...)` draws the vertical black line at ratio 1; the class names with their numbers of elements become the labels of the vertical axis; `invert_yaxis()` puts the first class at the top; and the horizontal axis runs from 10^{-9} to 3.

```
for i, n in enumerate(names):
    if classes[n]["max_ratio_to_U123"] == 0.0:  # mark a class that agrees exactly
        ax.text(1.5e-8, i, "exactly 0", va="center", fontsize=8)
ax.set_xlabel("largest $|R_{123} - R_{234}|$ / $U_{123}$ of the class")
ax.set_title("Fourth-grid test of the uncertainty (N136_lamp2_a20)")
```

```
save_figure(fig, "uncertainty_validated",
            "Validation of the reference uncertainty on a fourth grid for the state "
            "N136_lamp2_a20: for each of the 19 classes of quantities (the number of "
            "elements in brackets) the largest change of the three-grid value between "
            "the grids $(300, 600, 1200)$ and $(600, 1200, 2400)$, divided by the "
            "stated uncertainty $U_{123}$, on a logarithmic axis; a class that agrees "
            f"exactly is drawn at $10^{{-8}}$ and marked. All bars end left of the "
            "line 1; the largest, "
            f"{classes[worst]['max_ratio_to_U123']:.3f}, is the value of $p_0$ at the "
            "tip, where the densities are largest.")
```

The loop writes "exactly 0" next to every class whose ratio is exactly zero (here only the integral of p_3). After the axis label and the title, `save_figure` saves Figure 16a.2. The caption is an f-string that inserts the largest ratio, `{{-8}}` writing a literal pair of braces. What the student should see: every bar ends left of the line 1. The energies, the integrals and the levels end far to the left (ratios between about 10^{-4} and 3×10^{-3}, and exactly 0 for the integral of p_3), and the two values at the brane even further left (about 2×10^{-6}). Only the two values at the tip (ρ: 0.438, p_0: 0.787) and four of the five profiles, which include the tip as their first point (n: 0.661, ρ: 0.438, p_3: 0.437, p_0: 0.787; for ρ and p_0 the largest ratio is the tip value itself), come within a factor of about 2 of the line; the profile of S stays at 0.022. The largest ratio (p_0 at the tip, 0.787) is within a factor of 1.3 of the line. The tip, where the densities are largest, is where the grids work hardest. (All these ratios are printed in Out [7].)

In [10], every level converges like h^2 (Figure 16a.3).

```
level_points = []  # (state, level energy, ratio) of every level with a ratio
for sid in GROUND_IDS:
    eps = [PER_GRID[(sid, G)] for G in (300, 600, 1200)]
    ratios = RR.asym_ratio(*eps)  # the reference's own function
    stored = NEW[sid]["consistency"]["ratio_eps"]
    mine = (len(ratios), float(np.median(ratios)), min(ratios), max(ratios))
    say(f"{sid}: {mine[0]} levels, median ratio {mine[1]:.6f}, smallest "
        f"{mine[2]:.6f}, largest {mine[3]:.6f}")
    check(mine == (stored["count"], stored["median"], stored["min"], stored["max"])
          and abs(mine[1] - 4.0) <= 0.05,
          f"the levels of {sid} converge like h^2 (median ratio within 0.05 of 4)",
          record=f"{KS}/reports/ks-reference.json, check richardson_asymptotic_ratio")
```

For each ground state `eps` is the list of the level arrays on the three grids kept by the wrapper of In [4], and `RR.asym_ratio` (the reference's own function) computes the convergence ratio of Section 16.4 for every level whose two differences exceed 10^{-10} (smaller differences are dominated by rounding). `mine` collects the number of ratios, their **median** (the middle value when they are sorted; `np.median`), the smallest and the largest, and prints them. The check requires these four numbers to equal the ones the program stored in the entry `consistency` of the result, and the median to lie within 0.05 of 4, the criterion of the reference's check `richardson_asymptotic_ratio`. Out [10] shows medians of 4.000053, 4.000064 and 4.000055.

```
    floor = 1e-10  # the same selection as asym_ratio: both differences above 1e-10
    d1, d2 = eps[0] - eps[1], eps[1] - eps[2]
    keep = (np.abs(d1) > floor) & (np.abs(d2) > floor)
```

```
    energies = np.asarray(NEW[sid]["levels"]["eps"])[keep]
    level_points += [(sid, e, r) for e, r in zip(energies, d1[keep] / d2[keep])]
```

The same selection by hand, to draw it: `d1` and `d2` are the two differences of every level (numpy subtracts arrays entry by entry), `keep` is a **mask**, an array of truth values that is true where both differences exceed the floor (`&` combines two masks with "and"), and `energies` are the Richardson values of the kept levels (`array[keep]` keeps the entries where the mask is true). `level_points` collects one tuple (state, level energy, ratio) per level.

```
fig, ax = plt.subplots(figsize=(7.5, 4.3))
for colour, sid in zip(PALETTE, GROUND_IDS):
    pts = [(e, abs(r - 4.0)) for s, e, r in level_points if s == sid]
    ax.semilogy([p[0] for p in pts], [p[1] for p in pts], "o", color=colour, ms=4,
                alpha=0.8, label=f"{sid} ({len(pts)} levels)")
ax.axhline(0.05, color="k", lw=1.0, ls="--", label="limit 0.05 of the median test")
ax.set_xlabel("level energy $\\varepsilon$ (Richardson value, units of $m$)")
ax.set_ylabel("$|$ratio $- 4|$")
ax.set_title("Every level converges like $h^2$")
ax.legend(fontsize=8)
```

The figure draws, for each state, the distance of every ratio from 4 against the level energy, on a logarithmic vertical axis (`semilogy`), with the limit 0.05 of the median test as a dashed line. Two backslashes in a Python string give one backslash in the text, so `"\\varepsilon"` reaches matplotlib as the LaTeX command for ε.

```
worst_level = max(abs(r - 4.0) for _, _, r in level_points)
save_figure(fig, "eigenvalue_ratios",
            "Distance from 4 of the convergence ratio $(x(300) - x(600))/(x(600) - "
            "x(1200))$ of every level of the three ground states, against the "
            "level energy in units of $m$ (vertical axis logarithmic). A ratio of 4 "
            "means an error proportional to $h^2$. Most levels lie between "
            "$10^{-5}$ and $3\\times10^{-4}$ from 4, with no trend in the energy; "
            "the levels nearest $\\varepsilon = 0$ deviate by $5\\times10^{-4}$ to "
            "$7\\times10^{-4}$. The largest deviations belong to a group of levels "
            "of N136_lamp2_a20 between $\\varepsilon = 1.2$ and $2.1$; even the worst "
            f"level, at {worst_level:.4f}, stays below the limit 0.05 that the "
            "reference applies to the median.")
check(worst_level < 0.05, "every single level has a ratio within 0.05 of 4")
```

`worst_level` is the largest distance from 4 of any single level (0.0336). `save_figure` saves Figure 16a.3, and the check requires every single level, not only the median, to lie within 0.05 of 4. What the student should see: most levels lie between 10^{-5} and 3×10^{-4} from 4 (the long band of N136_lamp2_a20 between $\varepsilon = 0.06$ and 1 lies at 4×10^{-5} to 8×10^{-5}), and there is no trend with the energy: the levels of N688_lam0_a00 up to $\varepsilon = 5.6$ stay between 7×10^{-6} and 2.2×10^{-4}, and the highest levels of N136_lamp2_a20, near $\varepsilon = 3.25$, come closest to 4 of all (5×10^{-7} to 3×10^{-6}). The levels nearest $\varepsilon = 0$ deviate by 5×10^{-4} (N8_lamm2_a00, its largest ratio 4.000506 of Out [10]) to 7×10^{-4}. The largest deviations, 10^{-3} to 0.034, belong to a group of levels of N136_lamp2_a20 between $\varepsilon = 1.2$ and 2.1. Section 16.4 says what such a deviation measures: the ratio is $4\,(1 + \frac{15}{16}\frac{d}{c}h^2)$, so $|\text{ratio} - 4| = \frac{15}{4}\,|\frac{d}{c}|\,h^2$. The worst deviation, 0.0336, therefore means

$|\frac{d}{c}|\,h^2 = 0.0336/3.75 = 0.009$ on the coarsest grid ($h = 0.01$): there the h^4 term of the error is about 1% of the h^2 term, still small, but much larger than for most levels, whose deviations of 10^{-5} to 3×10^{-4} mean $|\frac{d}{c}|\,h^2$ between 3×10^{-6} and 8×10^{-5}. Even the worst level stays below the dashed line.

In [11], the two thermal states.

```
for sid in THERMAL_IDS:
    NEW[sid] = RR.jsonable(RR.thermo_job(CO, SPECS[sid])["data"])
    th = NEW[sid]["thermo"]
    say(f"{sid}: {NEW[sid]['levels_in_set']} levels; mu = {th['mu']['value']:.13f} "
        f"(U {th['mu']['U']:.1e}), E = {th['E']['value']:.12f} (U {th['E']['U']:.1e}),"
        f" C_V = {th['C_V']['value']:.9f} (U {th['C_V']['U']:.1e})")
    check_reproduction(sid, NEW[sid], f"{KS}/reference/results/thermo/{sid}.json")
```

For each thermal state the reference's thermal job is run (it solves the state on the three grids at T and at four neighbouring temperatures), its result is turned into plain numbers and kept in `NEW`, and the chemical potential μ, the energy E and the heat capacity C_V are printed with their uncertainties (`:.13f`, `:.12f` and `:.9f` give 13, 12 and 9 decimals, `:.1e` one decimal in powers of ten). Then `check_reproduction` compares with the committed thermal file. Out [11]: for N8_lamm1_a00_T10, $\mu = 0.2100104497343$ ($U = 2.3 \times 10^{-12}$), and for N8_lam0_a15_T50, $\mu = -0.0304029805513$ and $C_V = 32.379779710$; both files are reproduced byte for byte. N8_lamm1_a00_T10 is the state in which the first cross-check failed (Section 16.20).

In [12], the Rust solver: canonical and refined runs.

```
SOLVER = rust_program(f"{KS}/solver/Cargo.toml", "revision_ks_solver")
RUN_FOLDER = Path(tempfile.mkdtemp(prefix="textbook_16a_"))  # a new, empty folder
```

`rust_program` (In [1]) builds the Rust solver with cargo, which takes a second when the program is up to date, and returns the path of the program, `SOLVER`. `tempfile.mkdtemp` creates a new, empty **temporary folder** in the place the operating system keeps for temporary files (outside the repository; its name starts with `textbook_16a_` and ends with random characters) and returns its name, which `Path` turns into a path: `RUN_FOLDER`. The raw outputs of the runs go there, so they never enter the repository.

```
def run_single(sid, refined):
    """Run `revision_ks_solver single` for state sid; return (results, profiles,
    the arguments without the output files)."""
    spec = SPECS[sid]
    margin = (0.2 if "T" in spec else 0.25) + 2.0 * spec["sigma"]
    stem = f"{sid}_{'refined' if refined else 'canonical'}"
    arguments = ["single", "--m", "1", "--lambda", repr(spec["lam"]),
                 "--a4", repr(spec["a4"]), "--N", repr(spec["N"]),
                 "--margin", repr(margin)]
    if "T" in spec:
        arguments += ["--T", repr(spec["T"])]
    if refined:
        arguments.append("--refined")
```

`run_single` runs the solver's command `single` for one state. The **margin** decides how many levels above the Fermi level the label set keeps: $0.25 + 2\sigma$ at $T = 0$ and $0.2 + 2\sigma$ at $T > 0$, exactly as in the cross-check's measurement program (`"T" in spec` asks whether the dictionary has the key `"T"`). `stem` is the base of the two output file names, the state id followed by `_canonical` or `_refined`. `arguments` is the list of the program's arguments: the command, the mass 1, the coupling, the slice, N and the margin, each number written with `repr` (the shortest decimal text that gives back exactly the same double); a thermal state adds its temperature, and a refined run adds the option that switches to the refined numerics of Section 16.6.

```
    files = ["--out", f"{RUN_FOLDER / stem}.json",
             "--profiles", f"{RUN_FOLDER / stem}.csv"]
    done = subprocess.run([str(SOLVER)] + arguments + files, cwd=str(REPO),
                          capture_output=True, text=True)
    if done.returncode != 0 or not done.stdout.strip().endswith("SUCCESS"):
        print(done.stderr[-2000:])
        raise RuntimeError(f"the Rust run {stem} failed")
    results = json.loads((RUN_FOLDER / f"{stem}.json").read_text(encoding="utf-8"))
    with open(RUN_FOLDER / f"{stem}.csv", newline="", encoding="utf-8") as handle:
        profiles = [{k: float(v) for k, v in row.items()}
                    for row in csv.DictReader(handle)]
    return results, profiles, arguments
```

`files` adds the two output options: a JSON file with the energies, levels and integrals, and a CSV file with the profiles, both in `RUN_FOLDER` (`RUN_FOLDER / stem` joins the folder and the name). `subprocess.run` runs the program from the repository folder (`cwd=...`) and keeps its messages. If the program failed (a return code other than 0, or a last line other than SUCCESS; `.strip()` removes blanks and line ends), the function prints the end of the error messages and stops. Otherwise it reads the JSON file back and reads the CSV file as a list of rows, each a dictionary from the column names to numbers (`float(v)` turns each text into a number). It returns the two and the argument list.

```
RUST = {}  # (state id, "canonical" or "refined") -> (results, profiles)
for sid in SPECS:
    for refined in (False, True):
        results, profiles, arguments = run_single(sid, refined)
        RUST[(sid, "refined" if refined else "canonical")] = (results, profiles)
    say("revision_ks_solver " + " ".join(arguments))  # the refined command
shutil.rmtree(RUN_FOLDER)  # delete the temporary folder and the raw outputs in it
check(len(RUST) == 10, "ten Rust runs (five states, two numerics) completed")
```

The double loop runs every state twice, canonical (`refined` false) and refined (true), and keeps the results in the dictionary `RUST` under the pair (state id, kind). After each state it prints the refined command without the output files (whose folder differs from run to run): Out [12]. All results are now held in `RUST`, so `shutil.rmtree` deletes the temporary folder with everything in it (`rmtree` removes a whole folder tree); the runs leave no file behind. The check confirms ten runs.

In [13], do the runs reproduce the committed Rust results?

```
SUMMARY = {r["id"]: r for r in read_csv(f"{KS}/results/ground/summary.csv")}
EMT = {r["id"]: r for r in read_csv(f"{KS}/results/ground/emt-integrals.csv")}
```

```
EXCITED = {r["id"]: r for r in read_csv(f"{KS}/results/excited/summary.csv")}
ADIABATIC = {r["id"]: r for r in read_csv(f"{KS}/results/adiabatic/adiabaticity.csv")}
THERMO = {r["id"]: r for r in read_csv(f"{KS}/results/thermo/thermodynamics.csv")}
REFINEMENT = {(s["kind"], s["id"]): s
              for s in read_json(f"{KS}/checker/rust-refinement.json")["states"]}
```

The committed canonical Rust results are read: the ground-state summary, the energy-momentum integrals, the excited-state summary, the adiabaticity table and the thermodynamics table, each filed under the state id. `REFINEMENT` holds the cross-check's measurement file `rust-refinement.json`, filed under the pair (kind, id).

```
def rel(a, b):
    """|a - b| relative to max(1, |b|)."""
    return abs(a - b) / max(1.0, abs(b))

def level_map(results):
    """{(n2, j, parity, label): eps} of the levels of a ‘single‘ run."""
    return {tuple(l[:4]): l[4] for l in results["levels_n2_j_parity_label_eps_deg_f"]}
```

`rel(a, b)` is the difference of `a` and `b` relative to $\max(1, |b|)$. `level_map` turns the list of levels of a single run (each level a list of n_2, j, parity, label, energy, degeneracy, occupation) into a dictionary from the first four entries (`tuple(l[:4])`, the key of the level) to its energy (`l[4]`).

```
for sid in SPECS:
    canon, canon_prof = RUST[(sid, "canonical")]
    refined, _ = RUST[(sid, "refined")]
    if sid in GROUND_IDS:
        worst = rel(canon["E_KS"], float(SUMMARY[sid]["E_KS"]))
        integrals = canon["emtIntegrals_2Vol7_int_e6Hy"]
        for k in ("rho", "p3", "p_t", "p0", "n"):
            worst = max(worst, rel(integrals[k], float(EMT[sid]["int_" + k])))
        committed = {(int(x["n2"]), int(x["j"]), x["parity"], int(x["label"])):
                     float(x["eps"])
                     for x in read_csv(f"{KS}/results/ground/levels/{sid}.csv")}
        mine = level_map(canon)
        worst = max([worst] + [abs(mine[k] - committed[k]) for k in mine
                               if k in committed])
        stored_prof = read_csv(f"{KS}/results/ground/profiles/{sid}.csv")
        for name in ("n", "S", "rho", "p3", "p_t", "p0"):
            top = max(abs(float(row[name])) for row in stored_prof)
            worst = max([worst] + [abs(a[name] - float(b[name])) / max(top, 1e-300)
                                   for a, b in zip(canon_prof, stored_prof)])
        kind = "ground"
```

For each state the canonical and refined results are taken from `RUST` (`refined, _ = ...` drops the refined profiles, which are not needed here). For a ground state `worst` collects the largest difference between the canonical run and the committed results: E_{KS} relative; the five energy-momentum integrals relative; every level present in both (`committed` is a dictionary from the level key to the committed energy, read from the state's levels file); and every point of six profiles, measured relative

to the largest value of that profile (`max(top, 1e-300)` avoids a division by zero for a profile that is zero everywhere).

```
    else:
        row = THERMO[sid]
        worst = max(rel(canon["E_KS"], float(row["E"])),
                    abs(canon["mu_or_fermi_level"] - float(row["mu"])),
                    abs(canon["entropy"] - float(row["entropy"]))
                    / max(1e-6, abs(float(row["entropy"]))))
        kind = "thermo"
```

For a thermal state `worst` is the largest of three differences: E relative, μ absolute, and the entropy relative to $\max(10^{-6}, |S|)$.

```
    rec = REFINEMENT[(kind, sid)]
    lc, lr = level_map(canon), level_map(refined)
    level_diff = max(abs(lc[k] - lr[k]) for k in lc if k in lr)
    e_diff = abs(canon["E_KS"] - refined["E_KS"])
    say(f"{sid}: largest difference from the committed results {worst:.1e}; "
        f"|canonical - refined|: E_KS {e_diff:.3e}, levels {level_diff:.3e}")
    same = (abs(e_diff - rec["scalars"]["E_KS"]["abs_diff"])
            <= 1e-12 * max(1.0, abs(canon["E_KS"]))
            and abs(level_diff - rec["levels"]["max_abs_diff"]) <= 1e-12)
    if kind == "thermo":
        mu_diff = abs(canon["mu_or_fermi_level"] - refined["mu_or_fermi_level"])
        same = same and abs(mu_diff - rec["scalars"]["mu"]["abs_diff"]) <= 1e-12
    check(worst <= 1e-12, f"the canonical run of {sid} reproduces the committed "
                          "Rust results",
          record=f"{KS}/reports/ks-crosscheck.json, check "
                 "rust_refinement_applies_to_matrix")
    check(same, f"canonical minus refined of {sid} reproduces the measured values",
          record=f"{KS}/checker/rust-refinement.json, state {kind} {sid}")
```

`rec` is the measurement of this state in `rust-refinement.json`. `level_diff` is the largest canonical-minus-refined difference over the levels present in both runs, and `e_diff` the difference of E_{KS}. The printed line (Out [13]) shows both and `worst`, which is exactly 0 in all five states. `same` asks whether these differences equal the recorded ones within 10^{-12}; for thermal states the difference of μ must also agree. The first check reproduces the cross-check's check `rust_refinement_applies_to_matrix`: the canonical run gives exactly the committed results, so the measured differences apply to them. The second reproduces the state's entry of the measurement file. For example N688_lam0_a00 has $|x_c - x_r| = 7.529 \times 10^{-10}$ for E_{KS}, the number used in Section 16.6.

In [14], the tolerance rule in a few lines.

```
RK4_FACTOR = 16.0 / 15.0  # canonical error = (16/15) |canonical - refined|
ROWS = []  # (class, case, x_Rust, x_ref, U_ref, U_Rust, tolerance, |diff|, ratio)

def compare(cls, case, x_rust, x_ref, u_ref, u_rust, scale=None):
    """The tolerance rule of the cross-check; returns the ratio."""
```

```
    scale = max(1.0, abs(x_ref)) if scale is None else scale
    tolerance = 3.0 * (u_ref + u_rust) + 1e-12 * scale
    diff = abs(x_rust - x_ref)
    ratio = diff / tolerance
    ROWS.append((cls, case, x_rust, x_ref, u_ref, u_rust, tolerance, diff, ratio))
    return ratio
```

RK4_FACTOR is the factor $\frac{16}{15}$ of Section 16.6. ROWS will hold one tuple per comparison. compare is the tolerance rule of Section 16.7: the scale is $\max(1, |x_{ref}|)$ unless a scale is given (for profile points), the tolerance is $3(U_{ref} + U_{Rust}) + 10^{-12}\cdot$scale, the difference is $|x_{Rust} - x_{ref}|$, and the ratio is their quotient. The function stores all nine numbers of the comparison in ROWS and returns the ratio.

```
PROFILE_NAMES = ("n", "S", "Q", "M_eff", "v_v", "e_int", "rho", "p3", "p_t", "p0")

def rust_uncertainties(sid):
    """U_Rust of every quantity reported by ‘single‘, for state sid."""
    (canon, cp), (refined, rp) = RUST[(sid, "canonical")], RUST[(sid, "refined")]
    U = {k: RK4_FACTOR * abs(canon[k] - refined[k])
         for k in ("E_KS", "E_band", "E_int", "entropy")}
    U["mu"] = RK4_FACTOR * abs(canon["mu_or_fermi_level"]
                               - refined["mu_or_fermi_level"])
    ci, ri = canon["emtIntegrals_2Vol7_int_e6Hy"], refined["emtIntegrals_2Vol7_int_e6Hy"]
    for k in ("rho", "p3", "p_t", "p0", "n"):
        U["int_" + k] = RK4_FACTOR * abs(ci[k] - ri[k])
    for k in ("rho", "p3", "p_t", "p0"):  # profile end points: brane and tip
        U[k + "_brane"] = RK4_FACTOR * abs(cp[-1][k] - rp[-1][k])
        U[k + "_tip"] = RK4_FACTOR * abs(cp[0][k] - rp[0][k])
    lc, lr = level_map(canon), level_map(refined)
    U["levels"] = RK4_FACTOR * max(abs(lc[k] - lr[k]) for k in lc if k in lr)
    for name in PROFILE_NAMES:  # (U of the profile, largest |value|)
        U["profile_" + name] = (
            RK4_FACTOR * max(abs(a[name] - b[name]) for a, b in zip(cp, rp)),
            max(abs(a[name]) for a in cp))
    return U
```

PROFILE_NAMES are the ten profiles of the record: n, S, Q, M_{eff}, v_v, e_{int}, ρ, p_3, p_t, p_0. rust_unc ertainties computes $U_{Rust} = \frac{16}{15}|x_c - x_r|$ for every quantity that the single runs report: the three energies and the entropy (a dictionary comprehension), μ, the five integrals, the values of ρ, p_3, p_t, p_0 at the brane (the last profile point, index -1) and at the tip (the first, index 0), the levels (one number: $\frac{16}{15}$ times the largest difference over all levels of the state), and for each profile a pair: $\frac{16}{15}$ times the largest difference over its points, and the largest value of the profile.

```
U_RUST = {sid: rust_uncertainties(sid) for sid in SPECS}
WIDE = REPORTS["cross-check"]["rust_matrix_wide_uncertainties"]
say("matrix-wide Rust differences: " + ", ".join(
    f"{k.replace('refined_', '')} {v:.2e}" for k, v in sorted(WIDE.items())))
```

U_RUST holds these uncertainties for the five states. WIDE is the dictionary of matrix-wide differences recorded in the cross-check report for the quantities that single runs do not report (Section 16.6);

the printed line lists them, with the prefix `refined_` removed from each name (`.replace`), sorted by name (Out [14]).

```
sid = "N8_lamm2_a00"  # one comparison, piece by piece
x_rust = float(SUMMARY[sid]["E_KS"])
x_ref = NEW[sid]["scalars"]["E_KS"]["value"]
u_ref = NEW[sid]["scalars"]["E_KS"]["U"]
u_rust = U_RUST[sid]["E_KS"]
ratio = compare("ground_energies", f"{sid} E_KS", x_rust, x_ref, u_ref, u_rust)
say(f"E_KS of {sid}: Rust {x_rust!r}, reference {x_ref!r}")
say(f"    |diff| = {abs(x_rust - x_ref):.3e}, U_ref = {u_ref:.3e}, "
    f"U_Rust = {u_rust:.3e}")
say(f"    tolerance = 3 (U_ref + U_Rust) + 1e-12 max(1, |x|) = {ROWS[-1][6]:.3e}, "
    f"ratio = {ratio:.4f}")
check(ratio <= 1.0, f"E_KS of {sid} agrees within the tolerance")
```

One comparison piece by piece: E_{KS} of N8_lamm2_a00 from the committed Rust summary and from the new reference result, with U_{ref} from the reference and U_{Rust} from the measurement. The three printed lines (Out [14]) are the numbers of the worked comparison of Section 16.7: difference 1.264×10^{-13}, $U_{ref} = 2.096 \times 10^{-12}$, $U_{Rust} = 1.214 \times 10^{-13}$, tolerance 7.651×10^{-12}, ratio 0.0165 (`ROWS[-1][6]` is the tolerance of the last comparison). The check requires the ratio to be at most 1.

In [15], the ground-state comparisons.

```
def rank_key(n2, j, parity, rank):
    """The level key n2:j:parity:rank as a text, for example 1:-1:even:2."""
    return f"{int(n2)}:{'+1' if int(j) > 0 else '-1'}:{parity}:{int(rank)}"
```

`rank_key` writes the key of a level as a text such as `1:-1:even:2`: the shell n_2, the block type with its sign, the parity and the **rank**. The rank numbers the levels of one sector from its lowest particle level, which gets rank 0, upwards $1, 2, \ldots$ and downwards $-1, -2, \ldots$; for the Rust solver it is the Pruefer label l of Chapter 15 minus l_{min}, the label of the lowest particle level of the sector, and the reference solver counts its levels in the same way (Section 16.13 works out the ranks of the free problem).

```
U_DSCF = RK4_FACTOR * WIDE["refined_delta_scf"]  # matrix-wide Delta-SCF uncertainty
for sid in GROUND_IDS:
    sc, U = NEW[sid]["scalars"], U_RUST[sid]
    for k in ("E_KS", "E_band", "E_int"):
        if not (sid == "N8_lamm2_a00" and k == "E_KS"):  # made in section 13
            compare("ground_energies", f"{sid} {k}", float(SUMMARY[sid][k]),
                    sc[k]["value"], sc[k]["U"], U[k])
    for k, u in (("HOMO", U["levels"]), ("LUMO", U["levels"]),
                 ("KS_gap", 2.0 * U["levels"])):
        compare("ground_homo_lumo_gap", f"{sid} {k}", float(SUMMARY[sid][k]),
                sc[k]["value"], sc[k]["U"], u)
```

`U_DSCF` is the matrix-wide Delta-SCF uncertainty. For each ground state: the three energies are compared (skipping E_{KS} of N8_lamm2_a00, which In [14] already compared), and HOMO, LUMO and the gap, each with the largest level uncertainty of the state, the gap with twice that (it is a difference of two levels).

```
    rust_levels = {}  # key -> (eps, occupation) of the committed Rust levels
    for x in read_csv(f"{KS}/results/ground/levels/{sid}.csv"):
        rank = int(x["label"]) - int(x["label_min"])
        rust_levels[rank_key(x["n2"], x["j"], x["parity"], rank)] = (
            float(x["eps"]), float(x["f"]))
    lev = NEW[sid]["levels"]
    ref_levels = {rank_key(*k): (e, u, f)
                  for k, e, u, f in zip(lev["keys"], lev["eps"], lev["U"], lev["f"])}
    common = sorted(set(rust_levels) & set(ref_levels))
    for k in common:
        compare("ground_eigenvalues", f"{sid} level {k}", rust_levels[k][0],
                ref_levels[k][0], ref_levels[k][1], U["levels"])
```

The committed Rust levels of the state are read and filed under their keys, with the Rust label turned into a rank by subtracting `label_min`, the label of the lowest particle level of its sector; each entry holds the energy and the occupation. The reference levels are filed the same way, with energy, uncertainty and occupation (`zip` walks through four lists at once). `common` is the sorted list of the keys present in both (`&` of two sets is their common part), and every common level is compared with the level uncertainty of the state.

```
    occupied_rust = sorted(k for k, v in rust_levels.items() if v[1] > 0)
    occupied_ref = sorted(k for k, v in ref_levels.items() if v[2] > 0)
    compare("excited_delta_scf", f"{sid} delta_SCF", float(EXCITED[sid]["delta_SCF"]),
            sc["delta_SCF"]["value"], sc["delta_SCF"]["U"], U_DSCF)
    compare("excited_delta_scf", f"{sid} E_excited", float(EXCITED[sid]["E_excited"]),
            sc["E_excited"]["value"], sc["E_excited"]["U"], U["E_KS"] + U_DSCF)
    say(f"{sid}: {len(rust_levels)} Rust levels, {len(ref_levels)} reference levels, "
        f"{len(common)} compared; {len(occupied_rust)} occupied in both")
    check(occupied_rust == occupied_ref, f"the same occupied levels in {sid}",
          record=f"{KS}/reports/ks-crosscheck.json, check "
                 "ground_occupations_and_groups")
```

`occupied_rust` and `occupied_ref` are the sorted keys of the occupied levels of each solver. The Delta-SCF energy and the energy of the excited state are compared (the latter with the sum of the uncertainties of E_{KS} and of the Delta-SCF energy). The printed line (Out [15]) shows how many levels each solver kept and how many were compared: the Rust solver keeps more levels than the reference (64 against 22 for N8_lamm2_a00), and every reference level has a Rust partner. The check requires the same occupied levels, reproducing the check `ground_occupations_and_groups`.

In [16], energy-momentum tensor and adiabaticity.

```
U_ADIABATIC = RK4_FACTOR * WIDE["refined_adiabatic_derivatives"]  # relative
for sid in GROUND_IDS:
    sc, U, e = NEW[sid]["scalars"], U_RUST[sid], EMT[sid]
    for k in ("rho", "p3", "p_t", "p0", "n"):
        compare("emt_integrals", f"{sid} int_{k}", float(e["int_" + k]),
                sc["int_" + k]["value"], sc["int_" + k]["U"], U["int_" + k])
    for k in ("rho", "p3", "p_t", "p0"):
        for end in ("brane", "tip"):
            name = f"{k}_{end}"
            compare("emt_brane_tip_values", f"{sid} {name}", float(e[name]),
                    sc[name]["value"], sc[name]["U"], U[name])
```

`U_ADIABATIC` is the matrix-wide relative uncertainty of the derivatives along the history. For each ground state the five integrals are compared, each with its measured U_{Rust}, and the four quantities ρ, p_3, p_t, p_0 at the brane and at the tip (eight comparisons; `name` is for example `rho_tip`).

```
stored = read_csv(f"{KS}/results/ground/profiles/{sid}.csv")
for name in PROFILE_NAMES:
    values = [float(row[name]) for row in stored]
    top = max(max(abs(v) for v in values), 1e-300)  # the scale of the profile
    ref = NEW[sid]["profiles"][name]
    for i, row in enumerate(stored):
        compare("ground_profiles", f"{sid} {name}(y = {float(row['y']):.2f})",
                values[i], ref["value"][i], ref["U"][i],
                U["profile_" + name][0], scale=top)
```

The committed Rust profiles of the state are read; for each of the ten profiles `top` is its largest value (the scale of Section 16.7) and `ref` the reference profile with its uncertainties. Every one of the 151 points is compared, its case named with the profile and the position, for example `rho(y = -3.00)`.

```
u_q, top_q = U["profile_Q"]
dex = float(e["deltaE_x_exact_fock"])
compare("exchange_delta_E_x", f"{sid} deltaE_x", dex,
        sc["deltaE_x_exact_fock"]["value"], sc["deltaE_x_exact_fock"]["U"],
        RK4_FACTOR * 2.0 * (u_q / RK4_FACTOR) / max(top_q, 1e-300) * abs(dex))
```

The exchange difference ΔE_x, with the uncertainty derived in Section 16.7: twice the relative uncertainty of the profile Q times $|\Delta E_x|$. The code multiplies by `RK4_FACTOR` and divides `u_q` by it again; the two factors cancel, and what remains is $2\,(U_Q / \max|Q|)\,|\Delta E_x|$, where U_Q already contains the factor $\frac{16}{15}$.

```
a = ADIABATIC[sid]
compare("adiabatic_dE_da4", f"{sid} dE_da4_emt", float(a["dE_da4_emt"]),
        sc["dE_da4_emt"]["value"], sc["dE_da4_emt"]["U"],
        3.0 * (U["int_p3"] + U["int_p_t"]))
fd = float(a["dE_da4_finite_difference"])
compare("adiabatic_dE_da4", f"{sid} dE_da4_finite_difference", fd,
        sc["dE_da4_fd"]["value"], sc["dE_da4_fd"]["U"], U_ADIABATIC * abs(fd))
q_rust, ad = float(a["Q_max"]), NEW[sid]["adiabatic"]
compare("adiabatic_Q_max", f"{sid} Q_max", q_rust, ad["Q_max"], ad["U_Q_max"],
        U_ADIABATIC * abs(q_rust))
```

The derivative dE/da_4 in its energy-momentum form, with the uncertainty $3(U_{I_3} + U_{I_t})$ derived in Section 16.7, and as a difference quotient, with the matrix-wide relative uncertainty. Then the adiabaticity measure Q_{max} of Chapter 15.

```
if q_rust > 0:
    top = ad["top"][0]  # the reference's maximising pair
    hole, particle = [s.strip() for s in a["Q_max_pair"].split("->")]
    say(f"{sid}: Q_max = {q_rust:.10f} for the pair {hole} -> {particle} (Rust), "
        f"{top['hole']} -> {top['particle']} (reference)")
```

```
        check((hole, particle) == (top["hole"], top["particle"]),
              f"both solvers find the same maximising pair in {sid}")
        me = float(a["Q_max_matrix_element"])
        compare("adiabatic_Q_max", f"{sid} Q_max matrix element", me,
                top["matrix_element"], top["U_matrix_element"], U_ADIABATIC * abs(me))
        compare("adiabatic_Q_max", f"{sid} Q_max delta eps", float(a["Q_max_delta_eps"]),
                top["delta_eps"], top["U_delta_eps"], 2.0 * U["levels"])
```

When Q_{max} is not zero (it is zero in both solvers for the states with $N = 8$: their eight quanta sit at zero 3-momentum, where the slice $a_{4,0}$ does not enter the equations, so every matrix element of the derivative along the history vanishes; `Revision/kohn_sham/reports/ks-crosscheck.json`, check `adiabatic_Q_max`), the maximising pair of levels must be the same in both solvers. The Rust table writes the pair as `hole -> particle`; `.split("->")` cuts the text at the arrow and `.strip()` removes the blanks. The printed lines (Out [16]) show $Q_{max} = 0.0934505917$ for N688_lam0_a00 and 0.0421562349 for N136_lamp2_a20, with the same pairs in both solvers; the check requires this. Then the matrix element and the level spacing of the pair are compared.

```
ground_rows = [r for r in ROWS if r[1].split()[0] in GROUND_IDS]
say(f"{len(ground_rows)} ground-state comparisons so far")
check(all(r[8] <= 1.0 for r in ground_rows),
      "every ground-state comparison of the subset passes the tolerance rule")
```

`ground_rows` are the comparisons whose case begins with a ground-state id (`.split()[0]` is the first word). Out [16] reports 5122 of them, and the check requires every ratio to be at most 1.

In [17], the thermal comparisons.

```
ROOT_TOLERANCE = RUST_PARAMS["numerics"]["rootTolerance"]  # 1e-13
U_HEAT = RK4_FACTOR * WIDE["refined_heat_capacity"]  # relative, matrix-wide
for sid in THERMAL_IDS:
    th, U, row = NEW[sid]["thermo"], U_RUST[sid], THERMO[sid]
    T, N = NEW[sid]["T"], NEW[sid]["N"]
    u_f = U["E_KS"] + T * U["entropy"]
    for k, u in (("mu", U["mu"]), ("E", U["E_KS"]), ("entropy", U["entropy"]),
                 ("F", u_f), ("Omega_direct", u_f + N * U["mu"]),
                 ("Omega_F_minus_muN", u_f + N * U["mu"])):
        compare("thermo_state_functions", f"{sid} {k}", float(row[k]),
                th[k]["value"], th[k]["U"], u)
```

`ROOT_TOLERANCE` is the Rust root tolerance 10^{-13}, read from its parameters, and `U_HEAT` the matrix-wide relative uncertainty of the heat capacity. For each thermal state, `u_f` is $U_F = U_E + T\,U_S$ (Section 16.7), and six state functions are compared: μ, E, S, F, and Ω in its two forms, both with $U_\Omega = U_F + N\,U_\mu$.

```
    dT = 0.01 * T
    for k in ("C_V", "C_V_from_dEdT", "minus_dFdT"):
        x = float(row[k])
        quotient = k != "C_V"  # a difference quotient of energies
        compare("thermo_derivatives", f"{sid} {k}", x, th[k]["value"],
```

```
            th[k]["U"] + (N * 1e-12 / dT if quotient else 0.0),
            U_HEAT * max(abs(x), 1e-6)
            + (N * ROOT_TOLERANCE / dT if quotient else 0.0))
```

The three derivatives with respect to T: $C_V = T\,dS/dT$ and the two difference quotients dE/dT and $-dF/dT$, for which the noise floors of Section 16.7 are added, $N \cdot 10^{-12}/dT$ to the reference and $N \cdot 10^{-13}/dT$ to the Rust solver, with $dT = 0.01\,T$ (`x if condition else y` takes `x` when the condition holds and `y` otherwise).

```
    r = next(r for r in ROWS if r[1] == f"{sid} mu")
    say(f"{sid}: mu Rust {r[2]!r}, reference {r[3]!r}, ratio {r[8]:.4f}")
thermal_rows = [r for r in ROWS if r[1].split()[0] in THERMAL_IDS]
say(f"{len(thermal_rows)} thermal comparisons; {len(ROWS)} comparisons in all")
check(len(ROWS) == 5140 and all(r[8] <= 1.0 for r in ROWS),
      "all 5140 comparisons of the subset pass the tolerance rule")
```

`next(...)` finds the comparison of μ of the state, and its two values and ratio are printed (Out [17]: for N8_lamm1_a00_T10 the two values of μ differ by 4.0×10^{-13}, ratio 0.0438). The last check counts all comparisons, 5140 (5122 ground and 18 thermal), and requires every ratio to be at most 1.

In [18], reproducing the committed cross-check report.

```
TABLE = {r["case"]: r for r in read_csv(f"{KS}/reports/ks-crosscheck-table.csv")}
matched, largest = 0, 0.0
for cls, case, *_, tolerance, diff, ratio in ROWS:
    if case in TABLE:
        matched += 1
        stored = TABLE[case]
        largest = max(largest, abs(ratio - float(stored["ratio"])))
        if abs(ratio - float(stored["ratio"])) > 6e-4 or \
                abs(tolerance - float(stored["tolerance"])) > 1e-3 * tolerance:
            say(f"differs: {case}: {ratio:.4f} vs {stored['ratio']}")
say(f"{matched} of our comparisons are rows of the committed table; the largest "
    f"difference of the ratio is {largest:.1e}")
check(matched == 97 and largest <= 6e-4,
      "our tolerances and ratios equal the 97 matching rows of the committed table",
      record=f"{KS}/reports/ks-crosscheck-table.csv")
```

The cross-check wrote every comparison of single numbers into its table `ks-crosscheck-table.csv` (levels and profile points are too many and appear only in the report). `TABLE` files the rows under their case names. The loop goes through our comparisons, unpacking each tuple into its class, case, tolerance, difference and ratio (`*_` collects the four middle entries, which are not needed); whenever a case is a row of the table, it counts it and compares our ratio and tolerance with the stored ones, which the table keeps with four significant digits. Out [18]: 97 of our comparisons are rows of the table, and the largest difference of a ratio is 5.0×10^{-5}. The check requires 97 matches within 6×10^{-4}.

```
WORST_CASES = {}  # class -> (worst ratio in the report, its case)
pattern = re.compile(r"worst \|diff\|/tolerance ([0-9.]+) \((.+?): Rust ")
```

```
for c in REPORTS["cross-check"]["checks"]:
    found = pattern.search(c["detail"])
    if found and c["name"] in ("ground_eigenvalues", "ground_profiles",
                               "emt_brane_tip_values", "adiabatic_Q_max",
                               "thermo_state_functions", "thermo_derivatives"):
        WORST_CASES[c["name"]] = (float(found.group(1)), found.group(2))
for cls, (ratio, case) in sorted(WORST_CASES.items()):
    mine = max((r for r in ROWS if r[0] == cls), key=lambda r: r[8])
    say(f"{cls}: report {ratio:.3f} ({case}); this notebook {mine[8]:.3f} "
        f"({mine[1]})")
    check(mine[1] == case and abs(mine[8] - ratio) <= 6e-4,
          f"the worst case of {cls} is reproduced",
          record=f"{KS}/reports/ks-crosscheck.json, check {cls}")
```

`re.compile` prepares a pattern that reads, from the detail sentence of a check of the cross-check report, the worst ratio and its case: `\|` is a literal vertical bar, and `(.+?)` captures the shortest text up to `:  Rust` (the question mark makes the match as short as possible). For six classes the worst ratio and case are kept in `WORST_CASES`. For each, `mine` is our comparison with the largest ratio in that class. Out [18] prints both: the worst case of the whole cross-check in each of the six classes is a comparison of our subset, with the same ratio (0.314, 0.495, 0.324, 0.495, 0.226, 0.284). The six checks require the same case and the same ratio within 6×10^{-4}.

In [19], the levels of N136_lamp2_a20 (Figure 16a.4).

```
rows = [r for r in ROWS if r[0] == "ground_eigenvalues"
        and r[1].startswith("N136_lamp2_a20 ")]
worst = max(rows, key=lambda r: r[8])
fig, ax = plt.subplots(figsize=(7.5, 4.3))
ax.semilogy([r[3] for r in rows], [max(r[8], 1e-6) for r in rows], "o",
            color=PALETTE[0], ms=4, alpha=0.8, label="one level of N136_lamp2_a20")
ax.semilogy([worst[3]], [worst[8]], "o", color=PALETTE[1], ms=9,
            label=f"largest ratio {worst[8]:.3f}: level "
                  f"{worst[1].split('level ')[1]}")
ax.axhline(1.0, color="k", lw=1.2, label="ratio 1: the tolerance")
ax.set_ylim(1e-6, 3.0)
ax.set_xlabel("level energy $\\varepsilon$ (reference value, units of $m$)")
ax.set_ylabel("$|\\varepsilon_{Rust} - \\varepsilon_{ref}|$ / tolerance")
ax.set_title(f"{len(rows)} levels of N136_lamp2_a20 compared")
ax.legend(fontsize=8, loc="lower right")
```

`rows` are the 354 level comparisons of N136_lamp2_a20 (`startswith` tests the beginning of the case name), and `worst` the one with the largest ratio. The figure draws each level's ratio against its reference energy on a logarithmic vertical axis (ratios below 10^{-6} raised to 10^{-6}), the worst level as a large orange circle with its key in the legend (`.split('level ')[1]` takes the text after `level`), and the line ratio 1.

```
save_figure(fig, "level_agreement",
            "Agreement of the two solvers for every level of the ground state "
            "N136_lamp2_a20 ($N = 136$, $\\lambda = +\\lambda_2$, $a_{4,0} = 2$): the "
            "difference of the two level energies divided by the tolerance $3(U_{ref} "
            "+ U_{Rust}) + 10^{-12}\\max(1, |\\varepsilon|)$, against the level energy "
```

```
            "in units of $m$ (vertical axis logarithmic; ratios below one millionth "
            "are drawn at $10^{-6}$). Every point lies below the line 1, so every "
            f"level passes; the largest ratio, {worst[8]:.3f}, is the largest of all "
            "9616 level comparisons of the full cross-check.")
check(len(rows) == 354 and worst[8] < 1.0,
      "all 354 levels of N136_lamp2_a20 agree within the tolerance")
```

`save_figure` saves Figure 16a.4. What the student should see: every point lies below the line 1. The ratios rise with the level energy, from below 10^{-4} near 0 to 0.324 for the level 1:-1:even:2 at 3.24, because the higher levels' orbitals oscillate faster and both solvers are less accurate there; the largest ratio is the largest of all 9616 level comparisons of the full cross-check. The check requires 354 levels and the largest ratio below 1.

In [20], the profile with the largest ratio (Figure 16a.5).

```
sid = "N8_lamm2_a00"
stored = read_csv(f"{KS}/results/ground/profiles/{sid}.csv")
y = np.array([float(row["y"]) for row in stored])
fig, (top, bottom) = plt.subplots(2, 1, figsize=(7.5, 6.6), sharex=True)
top.plot(y, [float(row["rho"]) for row in stored], color=PALETTE[0], lw=1.8,
         label="Rust solver")
top.plot(y[::5], NEW[sid]["profiles"]["rho"]["value"][::5], "o", color=PALETTE[1],
         ms=5, mfc="none", label="reference solver")
top.set_ylabel("$\\rho(y)$ (proper energy density, units of $m$)")
top.set_title("Energy density of N8_lamm2_a00")
top.legend(fontsize=8)
```

The committed Rust profiles of N8_lamm2_a00 are read, `y` holds the 151 positions $-3, -2.98, \ldots, 0$, and a figure with two panels one above the other is made (`sharex=True` gives them the same horizontal axis). The upper panel draws the Rust energy density as a line and the reference energy density at every fifth point (`[::5]`) as open circles (`mfc="none"`: no fill).

```
largest = 0.0
for colour, name in ((PALETTE[0], "rho"), (PALETTE[2], "p0")):
    ratios = [r[8] for r in ROWS if r[0] == "ground_profiles"
              and r[1].startswith(f"{sid} {name}(")]
    largest = max(largest, max(ratios))
    bottom.semilogy(y, np.maximum(ratios, 1e-6), "-", color=colour, lw=1.5,
                    label=f"profile {name}")
bottom.axhline(1.0, color="k", lw=1.2, label="ratio 1: the tolerance")
bottom.set_ylim(1e-6, 3.0)
bottom.set_xlabel("hidden coordinate $y$ (tip $y = -3$, brane $y = 0$)")
bottom.set_ylabel("$|$Rust $-$ reference$|$ / tolerance")
bottom.legend(fontsize=8, loc="center right")
fig.tight_layout()
```

The lower panel draws, for ρ and for p_0, the ratio of each of the 151 point comparisons against y (`np.maximum` raises the small ratios to 10^{-6} point by point), and the line ratio 1; `largest` keeps the largest ratio of the two profiles.

```
save_figure(fig, "profile_agreement",
            "The profile with the largest ratio of the whole cross-check. Top: the "
            "proper energy density $\\rho(y)$ of the ground state N8_lamm2_a00 "
            "($N = 8$, $\\lambda = -\\lambda_2$, $a_{4,0} = 0$) from the Rust solver "
            "(line) and the reference solver (circles), in units of $m$, against the "
            "hidden coordinate $y$. Bottom: the difference divided by the tolerance "
            "at each of the 151 points for $\\rho$ and $p_0$ (logarithmic). The "
            f"largest ratio, {largest:.3f}, is at the tip $y = -3$, where the "
            "densities are largest and both solvers are least accurate.")
```

`save_figure` saves Figure 16a.5. What the student should see: in the upper panel the energy density of this state is negative and steep near the tip (it reaches about -10.2 at $y = -3$) and practically zero over most of the interval, and the circles of the reference lie on the Rust line; in the lower panel the ratios fall from 0.495 at the tip to below 10^{-6} towards the brane. The largest ratio of the whole cross-check sits at the tip because that is where the densities, and with them both programs' errors, are largest.

In [21], who sets the tolerance? (Figure 16a.6).

```
groups = {"ground states, single numbers": [], "ground states, levels": [],
          "thermal states": []}
for r in ROWS:
    if r[0] == "ground_profiles" or r[4] <= 0.0 or r[5] <= 0.0:
        continue  # profile points are drawn elsewhere; a zero U has no logarithm
    if r[1].split()[0] in THERMAL_IDS:
        groups["thermal states"].append(r)
    elif r[0] == "ground_eigenvalues":
        groups["ground states, levels"].append(r)
    else:
        groups["ground states, single numbers"].append(r)
```

The comparisons are sorted into three groups for the figure: ground-state single numbers, ground-state levels and thermal states. Profile points are left out (they appear in Figure 16a.7), and so are comparisons in which one of the two uncertainties is exactly zero, because zero has no logarithm (`continue` skips to the next comparison).

```
fig, ax = plt.subplots(figsize=(6.6, 5.6))
for colour, (label, rows) in zip(PALETTE, groups.items()):
    ax.loglog([r[4] for r in rows], [r[5] for r in rows], "o", color=colour, ms=4,
              alpha=0.75, label=f"{label} ({len(rows)})")
span = np.array([1e-18, 1e-5])
ax.loglog(span, span, "k-", lw=1.0, label="$U_{Rust} = U_{ref}$")
ax.set_xlabel("$U_{ref}$ (Richardson uncertainty of the reference)")
ax.set_ylabel("$U_{Rust}$ (16/15 of canonical minus refined)")
ax.set_title("Who sets the tolerance?")
ax.legend(fontsize=8)
above = sum(1 for rows in groups.values() for r in rows if r[5] > r[4])
total = sum(len(rows) for rows in groups.values())
```

Each group is drawn as points at the position (U_{ref}, U_{Rust}) on logarithmic axes, with the diagonal $U_{Rust} = U_{ref}$ as a black line. `above` counts the points above the diagonal and `total` all points.

```
save_figure(fig, "uncertainty_budget",
            "The two uncertainties that make the tolerance, for every comparison of "
            "single numbers and of levels in the five states of the subset: the "
            "Richardson uncertainty $U_{ref}$ of the reference solver (horizontal) "
            "and the measured uncertainty $U_{Rust}$ of the Rust solver (vertical), "
            "both logarithmic and in the units of the quantity. Points above the "
            "diagonal are dominated by the Rust uncertainty, points below it by the "
            f"reference; {above} of the {total} points lie above it. Comparisons in "
            "which one uncertainty is exactly zero are left out.")
say(f"{above} of {total} drawn comparisons have U_Rust > U_ref")
check(total > 500, "the uncertainty budget has more than 500 comparisons")
```

`save_figure` saves Figure 16a.6, and the printed line (Out [21]) says that 547 of the 602 drawn comparisons have $U_{Rust} > U_{ref}$. What the student should see: most points lie above the diagonal, so in most comparisons the measured Rust uncertainty is the larger part of the tolerance. The reference uncertainties of the levels lie between their floor $2 \cdot 10^{-12}$ and about 4×10^{-10} (the largest, 3.5×10^{-10}, belongs to a high level of N688_lam0_a00; `Revision/kohn_sham/reference/results/ground/N688_lam0_a00.json`), while the Rust level uncertainties form horizontal rows, one value per state (the largest level difference of the state, Section 16.6). The reference, with its three grids and two Richardson steps, is usually the more accurate program, and the tolerance is set mainly by the Rust solver. The check requires more than 500 drawn comparisons.

In [22], all comparisons by class (Figure 16a.7).

```
classes = ["ground_energies", "ground_homo_lumo_gap", "ground_eigenvalues",
           "excited_delta_scf", "emt_integrals", "emt_brane_tip_values",
           "ground_profiles", "exchange_delta_E_x", "adiabatic_dE_da4",
           "adiabatic_Q_max", "thermo_state_functions", "thermo_derivatives"]
rng = np.random.default_rng(12345)  # fixed seed: the same picture in every run
fig, ax = plt.subplots(figsize=(9.0, 5.0))
worst_by_class = {}
```

`classes` lists the twelve classes of the cross-check that the subset fills. `rng` is a **random-number generator** with a fixed starting value (the **seed** 12345), so that the "random" numbers it gives are the same in every run and the figure is the same byte for byte. A figure of 9 by 5 inches is made, and `worst_by_class` will hold each class's largest ratio.

```
for i, cls in enumerate(classes):
    ratios = np.array([r[8] for r in ROWS if r[0] == cls])
    jitter = rng.uniform(-0.28, 0.28, size=len(ratios))
    ax.semilogy(i + jitter, np.maximum(ratios, 1e-6), "o", color=PALETTE[0], ms=2.5,
                alpha=0.35)
    worst_by_class[cls] = float(ratios.max())
    ax.semilogy([i], [max(ratios.max(), 1e-6)], "D", color=PALETTE[1], ms=7)
    ax.text(i, 1.6, f"{len(ratios)}", ha="center", fontsize=7)
```

For each class `ratios` is the array of its ratios. `rng.uniform(-0.28, 0.28, size=...)` gives one random number between -0.28 and 0.28 per ratio; adding it to the class's position spreads the dots a little sideways so that they do not hide one another (**jitter**). The dots are drawn small and half transparent (`alpha=0.35`), the class's largest ratio as an orange diamond, and the number of comparisons of the class as a small text above the plot area.

```
ax.axhline(1.0, color="k", lw=1.2)
ax.set_xticks(range(len(classes)))
ax.set_xticklabels([c.replace("_", " ") for c in classes], rotation=40, ha="right",
                   fontsize=8)
ax.set_ylim(1e-6, 4.0)
ax.set_ylabel("$|x_{Rust} - x_{ref}|$ / tolerance")
ax.set_title("All comparisons of the subset (number of comparisons above each class)")
fig.tight_layout()
```

The line ratio 1 is drawn; the class names, with underscores replaced by blanks, are written under their positions, turned by 40 degrees and aligned at their right ends; the vertical axis runs from 10^{-6} to 4.

```
top_class = max(worst_by_class, key=worst_by_class.get)
save_figure(fig, "ratios_by_class",
            f"All {len(ROWS)} comparisons of the five states of the subset, grouped "
            "by the class of the cross-check: each dot is one ratio of the difference "
            "of the two solvers to the tolerance (logarithmic; ratios below "
            "$10^{-6}$ drawn at $10^{-6}$), the diamond is the largest ratio of the "
            "class, the number above a class counts its comparisons, and the black "
            "line is the tolerance. Every dot lies below it; the largest ratio, "
            f"{worst_by_class[top_class]:.3f}, belongs to the tip value of the energy "
            "density of N8_lamm2_a00.")
for cls in classes:
    say(f"  {cls:24s} largest ratio {worst_by_class[cls]:.4f}")
top_row = max(ROWS, key=lambda r: r[8])  # the comparison with the largest ratio
say(f"the largest ratio of the subset: {top_row[8]:.4f} ({top_row[1]})")
check(max(worst_by_class.values()) < 0.5
      and top_row[1] == "N8_lamm2_a00 rho_tip",
      "no comparison uses half of its tolerance; the largest is rho at the tip")
```

`top_class` is the class with the largest ratio (`max` with `key=worst_by_class.get` compares the classes by their values). `save_figure` saves Figure 16a.7, the loop prints each class's largest ratio (Out [22]), and `top_row` is the single comparison with the largest ratio of all 5140: 0.4952, the energy density at the tip of N8_lamm2_a00. What the student should see: every dot of every class lies below the line 1; the 4530 profile points fill a dense column from 10^{-6} to just below 0.5; and no class comes closer to the line than about one half. The check requires every largest ratio below 0.5 and the overall largest at `N8_lamm2_a00 rho_tip`.

In [23], the last check.

```
figure_files = [f"{FIGURE_FOLDER}/16a_{k}_{name}.png" for k, name in enumerate(
    ["grid_convergence", "uncertainty_validated", "eigenvalue_ratios",
     "level_agreement", "profile_agreement", "uncertainty_budget",
     "ratios_by_class"], start=1)]
check(all(output_file(f).is_file() for f in figure_files),
      "every figure file of this notebook exists")
all_checks_passed()
```

`enumerate(..., start=1)` numbers the seven figure names from 1, and the list comprehension builds their file names, for example `Revision/textbook/figures/16a_1_grid_convergence.png`.

The check confirms that each file exists where the notebook writes (`output_file`), and `all_checks_passed()` prints the last line, ALL 51 CHECKS PASSED (notebook 16a): three checks each in In [2], In [5], In [6], In [7], In [15] and In [16], four in In [10], ten in In [13], seven in In [18], two in In [11], and one each in In [3], In [4], In [8], In [12], In [14], In [17], In [19], In [21], In [22] and In [23].

16.13 Inside the reference solver I: the free problem and its exact levels

Why a problem with known answers. A grid method can be tested best on a problem whose exact answers are known, because then its error can be measured directly instead of estimated. The Kohn-Sham problem has such a special case: no interaction ($\lambda = 0$, so $M = m$ and $v = 0$) and no 3-momentum ($k = 0$). We call it the **free problem at zero momentum**. With $k = 0$ the factor κ drops out of the equations of Section 16.3, and so does the slice $a_{4,0}$:

$$a' = Ma - j\varepsilon\, b, \qquad b' = j\varepsilon\, a - Mb,$$

with a constant $M > 0$ (in the numbers $M = m = 1$, $L = 3$). Its exact levels are derived in this section (in the record: `Revision/kohn_sham/ks-theory.json`, `boundaryConditions.exactK0Spectra`, verified by check bc_exact_k0_spectra of `Revision/kohn_sham/reports/ks-theory-python.json`; status PROVED). Notebook 16b checks the derivation with the symbolic algebra package sympy and uses the levels to measure the errors of the reference's grid.

Even parity, line by line. The conditions are $b(-L) = 0$ (tip) and $b(0) = 0$ (brane). Let $\varepsilon \neq 0$; recall $j = \pm 1$, so $j^2 = 1$.

$$j\, b' = \varepsilon\, a - jM\, b \quad \Longrightarrow \quad a = \frac{j\,(b' + Mb)}{\varepsilon}.$$

Rule: multiply the second equation by j (using $j^2 = 1$), move jMb to the left side and divide by ε.

$$\frac{j\,(b'' + Mb')}{\varepsilon} = M\,\frac{j\,(b' + Mb)}{\varepsilon} - j\varepsilon\, b.$$

Rule: insert this a into the first equation $a' = Ma - j\varepsilon b$; the derivative of a is $j(b'' + Mb')/\varepsilon$ because M and ε are constants.

$$b'' + Mb' = Mb' + M^2 b - \varepsilon^2 b.$$

Rule: multiply both sides by ε/j (which equals $j\varepsilon$, since $1/j = j$).

$$b'' = -\left(\varepsilon^2 - M^2\right) b.$$

Rule: cancel Mb' on both sides and collect the terms with b.

If $\varepsilon^2 > M^2$, write $p^2 = \varepsilon^2 - M^2$ with $p > 0$. The equation $b'' = -p^2 b$ has the solutions $\alpha \sin(p(y + L)) + \beta \cos(p(y + L))$ (differentiate twice to check). The tip condition $b(-L) = 0$ gives $\beta = 0$, and since the equations are linear we may take $\alpha = 1$:

$$b = \sin\big(p\,(y+L)\big), \qquad b(0) = \sin(pL) = 0 \quad\Longrightarrow\quad p = \frac{n\pi}{L},\ n = 1, 2, 3, \ldots$$

Rule: the sine vanishes exactly at the whole multiples of π. Hence the even levels are

$$\varepsilon = \pm\sqrt{M^2 + \Big(\frac{n\pi}{L}\Big)^2}, \qquad n = 1, 2, 3, \ldots$$

Rule: $\varepsilon^2 = M^2 + p^2$, and both signs of the square root are allowed. (For $\varepsilon^2 \le M^2$ the solutions with $b(-L) = 0$ are $\sinh(q(y+L))$ or $y + L$, which do not vanish again at $y = 0$; so there are no other nonzero levels.) For $M = 1$, $L = 3$ the first one is $\sqrt{1 + (\pi/3)^2} = \sqrt{2.096623} = 1.447972$.

The zero mode, line by line. For $\varepsilon = 0$ the two equations no longer mix a and b:

$$a' = Ma, \qquad b' = -Mb \quad\Longrightarrow\quad a = A\,e^{My}, \qquad b = B\,e^{-My}.$$

Rule: the solution of $f' = cf$ is $f = f(0)\,e^{cy}$ (Chapter 2). The tip condition $b(-L) = B\,e^{ML} = 0$ forces $B = 0$, so $b = 0$ everywhere and the brane condition $b(0) = 0$ holds automatically: $\varepsilon = 0$ is an even level, the **zero mode**, whose orbital $a = A\,e^{My}$ grows towards the brane. Its normalisation $\int_{-L}^{0}(a^2 + b^2)\,dy = 1$ fixes A:

$$A^2\int_{-L}^{0} e^{2My}\,dy = A^2\Big[\frac{e^{2My}}{2M}\Big]_{-L}^{0} = A^2\,\frac{1 - e^{-2ML}}{2M} = 1 \quad\Longrightarrow\quad A = \sqrt{\frac{2M}{1 - e^{-2ML}}}.$$

Rule: the antiderivative of e^{2My} is $e^{2My}/(2M)$, evaluated at 0 and at $-L$; then solve for $A > 0$. For $M = 1$, $L = 3$: $A = \sqrt{2/(1 - e^{-6})} = 1.415970$.

Odd parity, line by line. Now the conditions are $b(-L) = 0$ and $a(0) = 0$. The derivation of $b'' = -(\varepsilon^2 - M^2)b$ did not use any brane condition, so again $b = \sin(p(y+L))$ and $a = j(b' + Mb)/\varepsilon$:

$$a = \frac{j\,\big(p\cos(p(y+L)) + M\sin(p(y+L))\big)}{\varepsilon}, \qquad a(0) = 0 \iff p\cos(pL) + M\sin(pL) = 0.$$

Rule: differentiate b ($b' = p\cos(p(y+L))$), insert, and set $y = 0$; the factor j/ε is not zero.

$$\tan(pL) = -\frac{p}{M}.$$

Rule: divide by $M\cos(pL)$ (which is not zero at a root: if $\cos(pL) = 0$ then $\sin(pL) = \pm 1$ and the left side would be $\pm M \neq 0$).

No odd level with $\varepsilon^2 \le M^2$, line by line. The sine above assumed $\varepsilon^2 > M^2$. We use the **hyperbolic sine and cosine**, $\sinh t = (e^t - e^{-t})/2$ and $\cosh t = (e^t + e^{-t})/2$: each is the derivative of the other, $\sinh 0 = 0$, and both are positive for $t > 0$. The three remaining cases give no level.

$$\varepsilon = 0: \qquad a = A\,e^{My}, \quad b = 0, \qquad a(0) = A = 0.$$

Rule: with $\varepsilon = 0$ the equations are $a' = Ma$ and $b' = -Mb$; as for the even zero mode, $b(-L) = 0$ gives $b = 0$ and $a = A\,e^{My}$; the odd brane condition $a(0) = 0$ then forces $A = 0$. Only the trivial solution $a = b = 0$ is left: odd parity has no zero mode.

$$0 < \varepsilon^2 < M^2: \qquad b = \sinh(q(y+L)), \qquad a(0) = \frac{j\,(q\cosh(qL) + M\sinh(qL))}{\varepsilon} \neq 0.$$

Rule: now $b'' = -(\varepsilon^2 - M^2)b = q^2 b$ with $q = \sqrt{M^2 - \varepsilon^2} > 0$, and $\sinh(q(y+L))$ solves it (differentiate twice) and vanishes at the tip; insert into $a = j(b' + Mb)/\varepsilon$ and set $y = 0$. Both terms of the bracket are positive, because q, M and L are positive, so $a(0) = 0$ is impossible.

$$\varepsilon^2 = M^2: \qquad b = y + L, \qquad a(0) = \frac{j\,(1 + ML)}{\varepsilon} \neq 0.$$

Rule: now $b'' = 0$, so b is a straight line, and the one that vanishes at the tip is $y + L$ (times a constant); insert as before, with $b' = 1$; $1 + ML > 0$. Hence every odd level has $|\varepsilon| > M$: the lowest positive odd level is $+\sqrt{M^2 + p_0^2} = 1.2923$, the bulk edge, and this is why odd parity has no zero mode (Section 16.19).

One root in each interval. Let $F(p) = M\sin(pL) + p\cos(pL)$ and $l = 0, 1, 2, \ldots$. At $pL = (l + \frac{1}{2})\pi$ we have cos $= 0$ and sin $= (-1)^l$, so $F = M(-1)^l$. At $pL = (l+1)\pi$ we have sin $= 0$ and cos $= (-1)^{l+1}$, so $F = p\,(-1)^{l+1}$. The two values have opposite signs, so F has a root p_l between them (a continuous function that changes sign has a zero in between: the intermediate value theorem). There is only one: on that interval $\tan(pL)$ increases from $-\infty$ to 0 while $-p/M$ decreases, so they meet once; and on the intervals $l\pi < pL < (l + \frac{1}{2})\pi$ there is none, because there $\tan(pL) > 0 > -p/M$. So the odd levels are $\varepsilon = \pm\sqrt{M^2 + p_l^2}$, $l = 0, 1, 2, \ldots$, with p_l the root in $((l + \frac{1}{2})\pi/L, (l+1)\pi/L)$. For $M = 1$, $L = 3$ the lowest is 1.292292828069 (Notebook 16b, Out [2]); this is the **bulk edge** of Chapter 15, the lowest level that does not belong to the brane band.

Ranks. The levels of one sector (one parity and one block type) are numbered from the lowest **particle** level, which gets the **rank** 0, upwards $1, 2, \ldots$ and downwards $-1, -2, \ldots$. By the convention of `ks-theory.json` the brane zero modes are particles. So for even parity rank 0 is the zero mode, rank $n \geq 1$ is $+\sqrt{M^2 + (n\pi/L)^2}$ and rank $-n$ its negative; for odd parity rank $r \geq 0$ is $+\sqrt{M^2 + p_r^2}$ and rank $-r - 1$ its negative. Notebook 16b computes the ranks -3 to 5 of both parities (Out [2]); for example the even levels of ranks 1 to 5 are 1.447972, 2.320881, 3.296908, 4.306502 and 5.330625.

16.14 Inside the reference solver II: the staggered grid and the matrix

The equations as an eigenvalue problem, line by line. A matrix method needs the equations in the form "level times orbital equals an operator applied to the orbital".

$$\varepsilon\, a = j\,(b' + Mb).$$

Rule: from the second equation $b' = j\varepsilon a - Mb$, multiply by j and move jMb over (as in Section 16.13).

$$\varepsilon\, b = j\,(-a' + Ma).$$

Rule: from the first equation $a' = Ma - j\varepsilon b$, multiply by $-j$ ($-ja' = -jMa + \varepsilon b$, using $j^2 = 1$) and solve for εb. (With a 3-momentum and a potential the record's operator is the same with $+jK + v$ added to the first line and $-jK + v$ to the second, $K = \kappa k$: `Revision/kohn_sham/reference/ks_fd.py`, its header.)

The staggered grid. Divide $-L \le y \le 0$ into G equal **cells** of width $h = L/G$. The cell ends, the **nodes**, are $y_i = -L + i\,h$ for $i = 0, \ldots, G$; the cell centres, the **half nodes**, are $y_{p+1/2} = -L + (p + \frac{1}{2})\,h$ for $p = 0, \ldots, G-1$. The reference stores a at the half nodes and b at the nodes: $u_p \approx a(y_{p+1/2})$ and $w_i \approx b(y_i)$. At the two end nodes b is zero for even parity ($w_0 = 0$ at the tip and $w_G = 0$ at the brane), so they are not unknowns. The unknowns, in the order of y, are

$$(u_0,\ w_1,\ u_1,\ w_2,\ \ldots,\ w_{G-1},\ u_{G-1}),$$

G values of u and $G-1$ values of w, $2G-1$ in all (Figure 16b.1 draws them for $G = 6$). Such a grid, on which the two components live on alternating points, is called **staggered**. On an ordinary grid, with both components at the same points and the centred difference $(f_{i+1} - f_{i-1})/(2h)$, a zigzag pattern $+1, -1, +1, \ldots$ has a difference of zero and produces spurious extra levels (the **doubling** problem of naive discretisations of Dirac-type equations; the record's reference README names it as the reason for the staggering, `Revision/kohn_sham/reference/README.md`). On the staggered grid every difference connects neighbours one half cell apart, and no such pattern escapes.

Centred differences and averages, line by line. Let f be a smooth function. Taylor's theorem (Chapter 2) gives

$$f(y \pm \tfrac{h}{2}) = f \pm \tfrac{h}{2}\, f' + \tfrac{h^2}{8}\, f'' \pm \tfrac{h^3}{48}\, f''' + \tfrac{h^4}{384}\, f'''' \pm \ldots,$$

Rule: $f(y+s) = f + sf' + \frac{s^2}{2} f'' + \frac{s^3}{6} f''' + \frac{s^4}{24} f'''' + \ldots$ with $s = \pm h/2$, so $\frac{s^2}{2} = \frac{h^2}{8}$, $\frac{s^3}{6} = \pm\frac{h^3}{48}$, $\frac{s^4}{24} = \frac{h^4}{384}$.

$$\frac{f(y + \frac{h}{2}) - f(y - \frac{h}{2})}{h} = f' + \frac{h^2}{24}\, f''' + \ldots$$

Rule: subtract the two expansions; the even terms cancel and the odd terms double ($2 \cdot \frac{h}{2} = h$, $2 \cdot \frac{h^3}{48} = \frac{h^3}{24}$), then divide by h.

$$\frac{f(y + \frac{h}{2}) + f(y - \frac{h}{2})}{2} = f + \frac{h^2}{8}\, f'' + \ldots$$

Rule: add the two expansions; now the odd terms cancel; divide by 2.

So the **centred difference** and the **centred average** of the two neighbours half a cell away are second-order approximations of f' and f at the midpoint, and their errors contain only even powers of h (the next terms are h^4, h^6, ...). This is where the even-power expansion of Section 16.4 comes from.

The rows of the matrix, line by line. Write the first eigenvalue equation at the half node $y_{p+1/2}$, the place where u_p lives; its neighbours of b are w_p and w_{p+1}:

$$\varepsilon\, u_p = j\Big(\frac{w_{p+1}-w_p}{h} + M\,\frac{w_p+w_{p+1}}{2}\Big) = j\Big(-\frac{1}{h}+\frac{M}{2}\Big)\,w_p + j\Big(\frac{1}{h}+\frac{M}{2}\Big)\,w_{p+1}.$$

Rule: replace b' by the centred difference and b by the centred average, then collect the coefficients of w_p and w_{p+1}. Write the second equation at the node y_i, where w_i lives; its neighbours of a are u_{i-1} and u_i:

$$\varepsilon\, w_i = j\Big(-\frac{u_i-u_{i-1}}{h} + M\,\frac{u_{i-1}+u_i}{2}\Big) = j\Big(\frac{1}{h}+\frac{M}{2}\Big)\,u_{i-1} + j\Big(-\frac{1}{h}+\frac{M}{2}\Big)\,u_i.$$

Rule: the same replacements for a' and a, then collect.

The matrix is tridiagonal and symmetric. In the order of the unknowns each row couples only to its two neighbours in the list (a u to the w on either side, a w to the u on either side), so the matrix T of the problem $Tz = \varepsilon z$ is **tridiagonal**; at $k = 0$ its diagonal is zero. It is also **symmetric** ($T_{rc} = T_{cr}$): the coefficient of w_{p+1} in the row of u_p is $j(\frac{1}{h}+\frac{M}{2})$, and the coefficient of u_p in the row of w_{p+1} (put $i = p+1$, so $u_{i-1} = u_p$) is the same number; likewise the coefficient of w_p in the row of u_p and of u_p in the row of w_p (put $i = p$) are both $j(-\frac{1}{h}+\frac{M}{2})$. So the entry between the neighbours number r and $r+1$ of the list is

$$T_{r,r+1} = T_{r+1,r} = \begin{cases} j\,(\frac{1}{h}+\frac{M}{2}) & r \text{ even (a } u \text{ followed by a } w), \\ j\,(-\frac{1}{h}+\frac{M}{2}) & r \text{ odd (a } w \text{ followed by a } u). \end{cases}$$

For $G = 4$ ($h = 0.75$) and $M = 1$ the two values are 1.8333 and -0.8333 (Notebook 16b, Out [4] prints the whole 7×7 matrix). Symmetry matters: a real symmetric matrix has only real eigenvalues and an orthonormal set of eigenvectors (the **spectral theorem**, quoted from linear algebra), as the levels of a self-adjoint problem must; and the counting method of Section 16.15 works only for symmetric matrices.

Odd parity: the rotated frame. For odd parity the brane condition is $a(0) = 0$, but a lives at half nodes, so no unknown sits at $y = 0$ to be set to zero. The reference rotates the two components before it discretises, so that both conditions become "b-type component zero at the ends" again. With the Pauli matrices $\sigma_1 = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$, $\sigma_2 = \begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix}$, $\sigma_3 = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}$ and the complex orbital $\chi = (a, ib)$ of Chapter 14, write $\chi = R\,\psi$ with $\psi = (u, iw)$ and $R = e^{i\phi\sigma_1}$ for an angle $\phi(y)$.

$$R = e^{i\phi\sigma_1} = \cos\phi + i\sin\phi\,\sigma_1.$$

Rule: the series $e^X = 1 + X + X^2/2 + \ldots$ with $X = i\phi\sigma_1$ and $\sigma_1^2 = 1$ splits into the even terms, the series of $\cos\phi$, and the odd terms, $i\sigma_1$ times the series of $\sin\phi$.

$$\begin{pmatrix} a \\ ib \end{pmatrix} = \begin{pmatrix} \cos\phi\, u + i\sin\phi\cdot iw \\ \cos\phi\cdot iw + i\sin\phi\, u \end{pmatrix} = \begin{pmatrix} \cos\phi\, u - \sin\phi\, w \\ i\,(\sin\phi\, u + \cos\phi\, w) \end{pmatrix}.$$

Rule: σ_1 exchanges the two components of (u, iw), and $i \cdot i = -1$. So $a = \cos\phi\, u - \sin\phi\, w$ and $b = \sin\phi\, u + \cos\phi\, w$. The reference chooses $\phi = j\,\frac{\pi}{2}\,\frac{y+L}{L}$: at the tip $\phi = 0$, so $b = w$ and $b(-L) = 0$ means $w(-L) = 0$; at the brane $\phi = j\pi/2$, so $\cos\phi = 0$, $\sin\phi = j$, $a = -j\,w$, and $a(0) = 0$ means $w(0) = 0$. Both conditions are again "$w = 0$ at the ends", and the same staggered grid works.

The rotated operator, line by line. The operator of Section 16.3 is $h_j = j[-i\sigma_1 \frac{d}{dy} + M\sigma_2 + K\sigma_3] + v$, and $h_j\chi = \varepsilon\chi$ becomes $R^{-1}h_j R\,\psi = \varepsilon\psi$, with $R^{-1} = \cos\phi - i\sin\phi\,\sigma_1$.

$$R^{-1}\Big(-i\sigma_1\frac{d}{dy}\Big)(R\psi) = -i\sigma_1(\psi' + R^{-1}R'\,\psi) = -i\sigma_1\psi' - i\sigma_1\cdot i\phi'\sigma_1\,\psi = -i\sigma_1\psi' + \phi'\,\psi.$$

Rule: the product rule $(R\psi)' = R'\psi + R\psi'$; σ_1 commutes with R; $R^{-1}R' = i\phi'\sigma_1$ (differentiate $e^{i\phi\sigma_1}$); and $-i\cdot i\cdot\sigma_1^2 = 1$. The derivative of the rotation adds the plain number ϕ'.

$$R^{-1}\sigma_2 R = (\cos\phi - i\sin\phi\,\sigma_1)(\cos\phi\,\sigma_2 + \sin\phi\,\sigma_3) = \cos 2\phi\,\sigma_2 + \sin 2\phi\,\sigma_3.$$

Rule: first $\sigma_2 R = \cos\phi\,\sigma_2 + i\sin\phi\,\sigma_2\sigma_1 = \cos\phi\,\sigma_2 + \sin\phi\,\sigma_3$ (because $\sigma_2\sigma_1 = -i\sigma_3$); then multiply out with $\sigma_1\sigma_2 = i\sigma_3$, $\sigma_1\sigma_3 = -i\sigma_2$, and use $\cos^2\phi - \sin^2\phi = \cos 2\phi$, $2\sin\phi\cos\phi = \sin 2\phi$. In the same way $R^{-1}\sigma_3 R = \cos 2\phi\,\sigma_3 - \sin 2\phi\,\sigma_2$ (Notebook 16b checks both with sympy, In [9]).

$$R^{-1}(M\sigma_2 + K\sigma_3)R = \big(M\cos 2\phi - K\sin 2\phi\big)\,\sigma_2 + \big(M\sin 2\phi + K\cos 2\phi\big)\,\sigma_3 = m_2\,\sigma_2 + k_2\,\sigma_3.$$

Rule: insert the two rotated matrices and collect the coefficients of σ_2 and σ_3. So the rotated operator has the same form, $j[-i\sigma_1\frac{d}{dy} + \phi' + m_2\sigma_2 + k_2\sigma_3] + v$, with the new mass m_2 and momentum term k_2. In the matrix, $j(\phi' + k_2) + v$ stands on the diagonal of the u rows and $j(\phi' - k_2) + v$ on the diagonal of the w rows (σ_3 is $+1$ on the first component and -1 on the second), and M in the neighbour entries is replaced by m_2, taken at the half node of the pair so that the matrix stays symmetric. For even parity $\phi = 0$, and everything reduces to the matrix above, with $\pm jK + v$ on the diagonal. The reference chooses the angle $j\phi$ for block type j so that the exact symmetry between the two block types at $k = 0$ survives on the grid: their levels agree exactly, to 0 in the record (`Revision/kohn_sham/reports/ks-reference.json`, check `free_k0_block_type_symmetry`).

16.15 Inside the reference solver III: counting eigenvalues, the zero mode and the brane band

The pivots, line by line. How does one find eigenvalue number i of a matrix with thousands of rows without computing all of them? By counting. Let T be tridiagonal with diagonal $d_1, \ldots, d_n$ and neighbour entries $o_1, \ldots, o_{n-1}$, and let x be a trial number. Write $T - x\mathbb{1}$ (where $\mathbb{1}$ is the unit matrix) as a product $\mathcal{L}D\mathcal{L}^T$, with $\mathcal{L}$ (a script letter, because L is the length 3 of the interval) having ones on its diagonal and one band below it, and D diagonal with entries $q_1, \ldots, q_n$, the **pivots**. For two rows:

$$\begin{pmatrix} d_1 - x & o_1 \\ o_1 & d_2 - x \end{pmatrix} = \begin{pmatrix} 1 & 0 \\ \ell & 1 \end{pmatrix}\begin{pmatrix} q_1 & 0 \\ 0 & q_2 \end{pmatrix}\begin{pmatrix} 1 & \ell \\ 0 & 1 \end{pmatrix} = \begin{pmatrix} q_1 & \ell q_1 \\ \ell q_1 & \ell^2 q_1 + q_2 \end{pmatrix}.$$

Rule: multiply the three matrices (row times column).

$$q_1 = d_1 - x, \qquad \ell = \frac{o_1}{q_1}, \qquad q_2 = d_2 - x - \ell^2 q_1 = d_2 - x - \frac{o_1^2}{q_1}.$$

Rule: compare the entries of the two sides, first the top left, then the off-diagonal, then the bottom right. The same comparison, row after row, gives for every n

$$q_1 = d_1 - x, \qquad q_r = d_r - x - \frac{o_{r-1}^2}{q_{r-1}} \quad (r = 2, \ldots, n).$$

Rule: each new row of $\mathcal{L}D\mathcal{L}^T$ involves only the previous pivot, because T has only one band on each side of the diagonal.

Sylvester's law of inertia and the Sturm count. A theorem of linear algebra that we quote without proof, **Sylvester's law of inertia**, says: if $A = \mathcal{L}D\mathcal{L}^T$ with an invertible $\mathcal{L}$, then A and D have the same number of negative eigenvalues. The eigenvalues of D are its diagonal entries, the pivots, and the eigenvalues of $T - x\mathbb{1}$ are $\varepsilon - x$ for the eigenvalues ε of T. Hence

$$c(x) = (\text{number of negative pivots}) = (\text{number of eigenvalues of } T \text{ below } x).$$

Rule: $\varepsilon - x < 0$ exactly when $\varepsilon < x$. The function $c(x)$ is the **Sturm count**; it jumps by one at every eigenvalue (Figure 16b.2 draws it as a staircase). If a pivot happens to be exactly zero, the next one would divide by zero; the reference then replaces it by the tiny negative number -10^{-290}, which is the same as moving x by a tiny amount. A worked example with three rows is Exercise 4 of Section 16.27.

Bisection. To find eigenvalue number i (counting from 0 at the lowest), start with an interval $[lo, hi]$ that contains every eigenvalue. Take the midpoint mid. If $c(mid) \le i$, at most i eigenvalues lie below mid, so eigenvalue number i lies at or above it: replace lo by mid; otherwise replace hi by mid. Each step halves the interval and keeps the eigenvalue inside, so no eigenvalue can be missed or counted twice. After n steps an interval of width W has shrunk to $W/2^n$; to reach a width τ one needs $n \ge \log_2(W/\tau)$ steps.

The starting interval: Gershgorin's bound, line by line. Let $Tz = \varepsilon z$ with $z \neq 0$, and let r be the row in which $|z_r|$ is largest.

$$(\varepsilon - T_{rr})\, z_r = \sum_{c \neq r} T_{rc}\, z_c.$$

Rule: row r of $Tz = \varepsilon z$, with the diagonal term moved to the left.

$$|\varepsilon - T_{rr}|\, |z_r| \le \sum_{c \neq r} |T_{rc}|\, |z_c| \le \Big(\sum_{c \neq r} |T_{rc}| \Big)\, |z_r|.$$

Rule: the triangle inequality, then $|z_c| \le |z_r|$ for every c.

$$|\varepsilon - T_{rr}| \le \rho_r = \sum_{c \ne r} |T_{rc}|.$$

Rule: divide by $|z_r| > 0$. So every eigenvalue lies within the **radius** ρ_r of some diagonal entry (Gershgorin's theorem), and the interval from $\min(d-\rho) - 1$ to $\max(d+\rho) + 1$ contains them all. For $G = 150$ ($h = 0.02$) the neighbour entries are 50.5 and -49.5, every inner radius is 100, and the interval is $[-101, 101]$, of width $W = 202$. The notebook stops when the width is below $10^{-14}\max(1, |lo|)$, so for a level near zero $\tau = 10^{-14}$ and $n \ge \log_2(202/10^{-14}) = 54.2$: 55 halvings, the number Notebook 16b prints (Out [5]).

The exact discrete zero mode, line by line. At $k = 0$ the grid problem keeps an eigenvalue that is exactly zero. Put $\varepsilon = 0$ and all $w_i = 0$. The rows of the u then read $0 = 0$. The row of w_i demands

$$\Big(\frac{1}{h} + \frac{M}{2}\Big)\, u_{i-1} + \Big(-\frac{1}{h} + \frac{M}{2}\Big)\, u_i = 0 \quad \Longrightarrow \quad u_i = q\, u_{i-1}, \qquad q = \frac{1 + Mh/2}{1 - Mh/2}.$$

Rule: multiply by h and solve for u_i. Hence $u_p = q^p\, u_0$: a discrete exponential, with $b = 0$ exactly, as in the continuum. How close is it to e^{My}?

$$\ln q = \ln\left(1 + \tfrac{Mh}{2}\right) - \ln\left(1 - \tfrac{Mh}{2}\right) = 2\Big(\tfrac{Mh}{2} + \tfrac{1}{3}\big(\tfrac{Mh}{2}\big)^3 + \dots\Big) = Mh + \frac{(Mh)^3}{12} + \dots$$

Rule: the series $\ln(1+t) = t - \frac{t^2}{2} + \frac{t^3}{3} - \dots$ with $t = \pm Mh/2$; in the difference the even powers cancel and the odd powers double. So $q^p = e^{p \ln q} = e^{Mph\,(1 + (Mh)^2/12 + \dots)}$: the exponent is M times the distance ph from the first half node, up to a relative error $(Mh)^2/12$, an error of order h^2. For $G = 150$ the grid values lie within 6.9×10^{-5} of $A\, e^{My}$ (Notebook 16b, Out [7]). In the record the zero mode's eigenvalue is at most 1.3×10^{-39} and the extrapolated profile agrees with $A\, e^{My}$ to 4.0×10^{-15} (`Revision/kohn_sham/reports/ks-reference.json`, check free_zero_mode).

The slope of the brane band: Hellmann-Feynman, line by line. Now switch on a small 3-momentum k. The zero mode moves away from zero and becomes the lowest level of the **brane band**, $\varepsilon \approx c\,k$ for small k (Chapter 15). Its slope $c = d\varepsilon/dk$ at $k = 0$ follows from a general fact about symmetric matrices. Let $T(k)z(k) = \varepsilon(k)z(k)$ with $z^T z = 1$, and write a prime for d/dk.

$$T'z + Tz' = \varepsilon' z + \varepsilon z'.$$

Rule: differentiate both sides with the product rule.

$$z^T T' z + z^T T z' = \varepsilon'\, z^T z + \varepsilon\, z^T z'.$$

Rule: multiply from the left by the row z^T.

$$z^T T' z + \varepsilon\, z^T z' = \varepsilon' + \varepsilon\, z^T z' \quad \Longrightarrow \quad \varepsilon' = z^T\, T'\, z.$$

Rule: $z^T T = (T^T z)^T = (Tz)^T = \varepsilon z^T$ because T is symmetric, and $z^T z = 1$; then cancel $\varepsilon z^T z'$. This is the **Hellmann-Feynman theorem** for matrices: the derivative of a level is the expectation

value of the derivative of the matrix. For even parity and $j = +1$ the momentum enters only the diagonal, $+\kappa(y)k$ in the u rows and $-\kappa(y)k$ in the w rows, so T' is diagonal with $\pm\kappa$. The zero mode has $w = 0$, and its normalised vector holds $u_p\sqrt{h}$, so

$$c = \sum_p \kappa(y_{p+1/2})\, u_p^2\, h \;\longrightarrow\; \int_{-L}^{0} \kappa\, a^2\, dy \quad (h \to 0).$$

Rule: only the u entries contribute; the sum is the midpoint rule for the integral. In the continuum, with $a = A\, e^{My}$ and $\kappa = e^{-Hy-a_{4,0}}$:

$$c = e^{-a_{4,0}} A^2 \int_{-L}^{0} e^{(2M-H)y}\, dy = e^{-a_{4,0}}\, \frac{2M}{1-e^{-2ML}}\, \frac{1-e^{-(2M-H)L}}{2M-H}.$$

Rule: $\kappa a^2 = e^{-a_{4,0}} A^2 e^{-Hy} e^{2My}$; integrate the exponential as for the normalisation; insert A^2 from Section 16.13. The theory file `Revision/kohn_sham/ks-theory.json` holds this formula under the name `checksNumeric.braneBandSlopeFormula`, and the record proves it in the check brane_band_slope of its Python report `Revision/kohn_sham/reports/ks-theory-python.json` (status PROVED). For $M = H = 1$ and $L = 3$ it gives:

$$c(0) = \frac{2\,(1-e^{-3})}{1-e^{-6}} = \frac{2 \cdot 0.950213}{0.997521} = 1.905148.$$

Rule: insert the numbers; $e^{-3} = 0.049787$ and $e^{-6} = 0.002479$.

The meaning of the factor $e^{-a_{4,0}}$. The weight $\kappa = e^{-Hy-a_{4,0}}$ is one over the 3-space scale factor $e^{a_4} \sin^{1/6} z = e^{a_4+Hy}$ (because $\sin z = e^{6Hy}$, so $\sin^{1/6} z = e^{Hy}$). Along the history $a_4 = AHx_4$ the 3-space scale factor grows while the three extra times deflate with e^{-a_4} (the 7-volume stays constant), and the energy carried by a 3-momentum is redshifted by $e^{-a_{4,0}}$: the brane band flattens. From slice to slice ($\Delta a_{4,0} = 0.5$) the slope shrinks by the factor $e^{-0.5} = 0.6065$: 1.905148, 1.155531, 0.700865, 0.425096, 0.257834. The reference's grid reproduces the formula to 2.6×10^{-15}, relative (`Revision/kohn_sham/reports/ks-reference.json`, check `free_brane_band_slope`).

16.16 Example: the reference method by hand (Notebook 16b)

Notebook 16b opens the reference solver and rebuilds its method by hand on the free problem of Section 16.13, where every answer is known: it derives the exact levels and checks them with sympy, draws the staggered grid, builds the matrix and checks it entry by entry against the reference's own function, finds eigenvalues with Sturm counts and bisection, constructs the exact discrete zero mode, treats the odd parity in the rotated frame, measures the convergence on five grids and the effect of one and two Richardson steps, computes the slope of the brane band at the five slices of the history, and finally runs the reference program's own free-field job and checks its six free-field criteria. It needs no Rust, runs in less than a minute, draws seven figures and ends with the line ALL 31 CHECKS PASSED (notebook 16b).

16.17 How to run Notebook 16b

Step 1. What this notebook does and what it needs.

Notebook 16b (The reference method by hand: staggered grid, Sturm counts, Richardson) is the file `Revision/textbook/notebooks/16b_staggered_grid.ipynb` of the repository Dirac_claude. It builds, line by line, the staggered finite-difference matrix that the independent reference solver uses, for the free Kohn-Sham orbital equation at zero 3-momentum, a problem whose levels are known exactly; it finds the levels by Sturm counts and bisection, shows that the grid error shrinks like the square of the cell width and that two Richardson steps remove it, constructs the exact discrete zero mode at the brane, computes the slope of the brane band at the five slices of the deflating history, and checks every number against the committed record of the reference solver, whose free-field checks it also runs again. It needs a computer with Windows 11, macOS or Linux, an internet connection for the installation, the program Git, and Python 3.12 or newer (the notebooks were built with Python 3.14.5) with these packages at exactly these versions: numpy 2.4.6, sympy 1.14.0, mpmath 1.3.0, matplotlib 3.11.0, jupyterlab 4.4.10, nbformat 5.10.4, nbclient 0.10.2, ipykernel 7.1.0 and nbconvert 7.16.6. The notebook itself imports numpy, sympy and matplotlib; the other packages run Jupyter, the program that shows and runs notebooks. It does not need Rust.

Step 2. Install Git and Python (once per computer).

A terminal is the window in which you type commands: on Windows the app Windows PowerShell (or Terminal), on macOS the app Terminal (it runs the shell zsh), on Linux any terminal (it runs the shell bash). Type every command of this section into a terminal exactly as printed, one line at a time, and press Enter after each line.

Windows: download Git from https://git-scm.com/download/win and install it with the default choices. Download Python from https://www.python.org/downloads/ and run the installer; in its first window tick the box "Add python.exe to PATH" before you click "Install Now".

macOS: download Python from https://www.python.org/downloads/ and run the installer. Then open the app Terminal and run this command, which installs Git and the compiler tools:

macOS (zsh):

```
xcode-select --install
```

Linux (Debian or Ubuntu; other distributions have packages of the same names): run these two commands:

Linux (bash):

```
sudo apt update
sudo apt install git python3 python3-venv
```

Then close the terminal and open a NEW one (a terminal opened before the installation does not know the new programs), and check the version of Python; it must print 3.12 or a higher number:

Windows (PowerShell):

```
py -3 --version
```

macOS (zsh) and Linux (bash):

```
python3 --version
```

If an older Linux prints a lower number (Ubuntu 22.04 has Python 3.10), install Python 3.12 with the following three commands, and in Step 3 type `python3.12` instead of `python3` in the command that creates the environment:

Linux (bash), only when the version is too low:

```
sudo add-apt-repository ppa:deadsnakes/ppa
sudo apt update
sudo apt install python3.12 python3.12-venv
```

Step 3. Get the repository and install the packages (once per computer).

The commands below download the repository (a few hundred megabytes; the folder then needs up to about 1 GB of disk space) into the folder Dirac_claude inside your home folder, create a private Python environment in the folder dirac-book-env inside your home folder (a private environment is a folder with its own copy of Python and of the packages, so that nothing else on your computer is changed), activate it (from then on the commands `python` and `jupyter` typed in this terminal are those of the environment, and the prompt starts with (dirac-book-env)), and install the packages at the pinned versions (this downloads about 90 MB and takes a few minutes; the environment takes about 400 MB of disk space). If you have done this step before, for this or for another notebook, skip it and go to Step 4; to get the newest version of the repository, run `git pull` in the repository folder after Step 4.

Windows (PowerShell):

```
cd $HOME
git clone https://github.com/once-ere/Dirac_claude.git
py -3 -m venv "$HOME\dirac-book-env"
Set-ExecutionPolicy -ExecutionPolicy RemoteSigned -Scope Process -Force
& "$HOME\dirac-book-env\Scripts\Activate.ps1"
python -m pip install --upgrade pip
python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
```

The line with `Set-ExecutionPolicy` allows PowerShell to run the activation script in this one window only; it changes nothing permanently.

macOS (zsh):

```
cd ~
git clone https://github.com/once-ere/Dirac_claude.git
python3 -m venv ~/dirac-book-env
source ~/dirac-book-env/bin/activate
python -m pip install --upgrade pip
python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
```

Linux (bash):

```
cd ~
git clone https://github.com/once-ere/Dirac_claude.git
python3 -m venv ~/dirac-book-env
source ~/dirac-book-env/bin/activate
python -m pip install --upgrade pip
python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
```

Step 4. In every new terminal: activate the environment and go into the repository folder.

Every later step starts in the repository folder with the environment active. Run these lines whenever you open a new terminal (they do no harm if the environment is already active):

Windows (PowerShell):

```
Set-ExecutionPolicy -ExecutionPolicy RemoteSigned -Scope Process -Force
& "$HOME\dirac-book-env\Scripts\Activate.ps1"
cd "$HOME\Dirac_claude"
```

macOS (zsh) and Linux (bash):

```
source ~/dirac-book-env/bin/activate
cd ~/Dirac_claude
```

Step 5. Run the notebook in JupyterLab.

In the repository folder, with the environment active, run these two lines (the first one goes into the folder of the notebooks):

Windows, macOS and Linux:

```
cd Revision/textbook/notebooks
jupyter lab 16b_staggered_grid.ipynb
```

JupyterLab opens in your web browser and shows the notebook (if no browser window opens, copy the address that starts with `http://localhost:8888/lab` from the terminal into the address bar of your browser). The name at the top right of the notebook must read Python 3 (ipykernel). Choose the menu Run > Run All Cells. While a cell runs, the label to its left shows `[*]`; when it has finished, the label shows a number. The notebook has finished when the last code cell shows a number; this takes about 45 seconds on a typical laptop. Scroll to the end and compare the last printed lines with the lines in the step "What the notebook writes and what you must see" below. To keep the results, save the notebook (menu File > Save Notebook). To stop JupyterLab, choose the menu File > Shut Down, or press Ctrl+C twice in the terminal.

Step 6. Or run the notebook without a browser (headless).

In the repository folder, with the environment active, run:

Windows, macOS and Linux:

```
cd Revision/textbook/notebooks
jupyter nbconvert --to notebook --execute --inplace 16b_staggered_grid.ipynb
```

This runs every cell from the top to the bottom and saves the results into the notebook file. A failed check stops it with an error message that contains AssertionError and the name of the check. If the command ends with a line that starts with `[NbConvertApp] Writing` and shows no error, every check passed; open the notebook with `jupyter lab 16b_staggered_grid.ipynb` (in the same folder, without running the cells again) to read the printed lines and see the figures.

Step 7. What the notebook writes and what you must see.

The notebook writes (or overwrites) these files:

- `Revision/textbook/figures/16b.captions.json`
- `Revision/textbook/figures/16b_1_staggered_grid.png`
- `Revision/textbook/figures/16b_2_sturm_staircase.png`
- `Revision/textbook/figures/16b_3_orbitals.png`
- `Revision/textbook/figures/16b_4_matrix_heat_maps.png`
- `Revision/textbook/figures/16b_5_convergence_ladder.png`
- `Revision/textbook/figures/16b_6_error_ratios.png`
- `Revision/textbook/figures/16b_7_brane_band_slope.png`

It changes no other file of the repository; running it headless or saving it in JupyterLab also rewrites the notebook file itself. It does not use the internet while it runs. The files it writes are the same files that are stored in the repository (on another computer a figure may differ in a few bytes, which is harmless). To get the stored versions back, run this command in the repository folder (it also undoes every change you made yourself in the folder Revision/textbook):

Windows, macOS and Linux:

```
git checkout -- Revision/textbook
```

Every check of the notebook prints a line that starts with PASS. At the end of the notebook (the output of its last code cell) you must see exactly these lines:

```
PASS every figure file of this notebook exists
ALL 31 CHECKS PASSED (notebook 16b)
```

and the notebook must show 7 figures below the cells that draw them.

Step 8. If something goes wrong.

- "ModuleNotFoundError: No module named ..." in the notebook: JupyterLab was started without the environment. Stop it (menu File > Shut Down), do Step 4, and start it again. If the error remains, another Python installation has registered its own kernel called python3; with the environment active, run the following command and start JupyterLab again:

```
python -m ipykernel install --user --name python3
```

- "FileNotFoundError: The repository folder was not found": the notebook was opened from a copy outside the repository. Open the file `Revision/textbook/notebooks/16b_staggered_grid.ipynb` inside the folder Dirac_claude.
- "fatal: destination path 'Dirac_claude' already exists" in Step 3: the repository was downloaded before; skip the line with `git clone`.
- Windows: "running scripts is disabled on this system": run the line with `Set-ExecutionPolicy` and then the activation line again. "py is not recognized": use `python` instead of `py -3`; "python is not recognized": install Python again and tick "Add python.exe to PATH".
- Linux: "ensurepip is not available" when the environment is created: run `sudo apt install python3-venv` and repeat Step 3.
- "jupyter is not recognized" or "command not found: jupyter": the environment is not active; do Step 4. If the environment is active and the message stays, the programs jupyter-lab and jupyter-nbconvert are not in the folders where the terminal looks for programs (`python -m jupyter` does not help then: it has to find the same programs). Start them through Python itself, in the folder of the notebook: the first command below does what `jupyter lab` does, the second what the headless command does:

```
python -m jupyterlab 16b_staggered_grid.ipynb
python -m nbconvert --execute --inplace 16b_staggered_grid.ipynb
```

- Windows: the headless run prints a RuntimeWarning that mentions the "Proactor event loop" and zmq: this is a message of the package pyzmq, not an error; the run continues normally.
- A red box with "Matplotlib is building the font cache; this may take a moment." in the first run after the installation: this is a message, not an error; the run continues and the message does not come again.
- An AssertionError names a check that failed: choose the menu Kernel > Restart Kernel and Run All Cells; if it fails again, install the packages again with the pip commands of Step 3, because a different package version can change the last digits of a result.
- The cell that computes the levels on five grids runs for a minute or longer: this is normal on a slow computer: the Sturm count is a loop over up to 4799 matrix rows, repeated about 60 times for every grid. Wait until the label shows a number.
- An AssertionError names a comparison with the record free-checks.json: the reference program or its record was changed. Get the stored versions back and run the notebook again.

```
git checkout -- Revision/kohn_sham
```

16.18 Notebook 16b: complete text

This section prints the complete text of the notebook file `Revision/textbook/notebooks/16b_staggered_grid.ipynb`: every cell in order, with the output that the stored, executed notebook holds. A text cell (Jupyter calls it a markdown cell) is printed in a frame after the label Text cell. A code cell is printed after the label In [k], where k is the number that Jupyter gives the cell when it runs it; the text that the cell prints follows after the label Out [k], and every figure that the cell draws follows as a figure with its caption.

Text cell:

```
## 1. What this notebook computes

Notebook 16a ran the reference solver as a finished program. This notebook opens
it up and rebuilds its method by hand on the one problem whose answers are known
exactly: the **free** orbital equation (no interaction, $\lambda = 0$) with zero
3-momentum ($k = 0$) and constant mass $M = m = 1$. Step by step it

- derives the exact levels of that problem (and checks the derivation with sympy);
- places the two components of an orbital on a **staggered grid** and turns the
  differential equation into a **symmetric tridiagonal matrix**, and checks that
  the matrix is exactly the one the reference program builds;
- finds the eigenvalues by **Sturm counts** and **bisection**, the method of the
  reference, and checks them against a standard eigenvalue routine;
- constructs the **exact zero mode** of the discrete problem by hand;
- treats the odd parity with the reference's **rotated frame**;
- shows on five grids that the error shrinks like $h^2$ and that two
  **Richardson** steps remove it down to rounding;
- computes the slope of the **brane band** at the five slices of the deflating
  history and compares it with the exact formula of `ks-theory.json`;
- runs the reference program's own free-field job again and checks that it
  reproduces the committed record and passes the six free-field checks.

It draws seven figures and runs in less than a minute.
```

Text cell:

```
## 2. How to run this notebook

**Step 1. What this notebook does and what it needs.**

Notebook 16b (The reference method by hand: staggered grid, Sturm counts, Richardson) is
the file `Revision/textbook/notebooks/16b_staggered_grid.ipynb` of the repository
Dirac_claude. It builds, line by line, the staggered finite-difference matrix that the
independent reference solver uses, for the free Kohn-Sham orbital equation at zero
3-momentum, a problem whose levels are known exactly; it finds the levels by Sturm counts
and bisection, shows that the grid error shrinks like the square of the cell width and
that two Richardson steps remove it, constructs the exact discrete zero mode at the
brane, computes the slope of the brane band at the five slices of the deflating history,
and checks every number against the committed record of the reference solver, whose
free-field checks it also runs again. It needs a computer with Windows 11, macOS or
Linux, an internet connection for the installation, the program Git, and Python 3.12 or
```

newer (the notebooks were built with Python 3.14.5) with these packages at exactly these versions: numpy 2.4.6, sympy 1.14.0, mpmath 1.3.0, matplotlib 3.11.0, jupyterlab 4.4.10, nbformat 5.10.4, nbclient 0.10.2, ipykernel 7.1.0 and nbconvert 7.16.6. The notebook itself imports numpy, sympy and matplotlib; the other packages run Jupyter, the program that shows and runs notebooks. It does not need Rust.

Step 2. Install Git and Python (once per computer).

A terminal is the window in which you type commands: on Windows the app Windows PowerShell (or Terminal), on macOS the app Terminal (it runs the shell zsh), on Linux any terminal (it runs the shell bash). Type every command of this section into a terminal exactly as printed, one line at a time, and press Enter after each line.

Windows: download Git from https://git-scm.com/download/win and install it with the default choices. Download Python from https://www.python.org/downloads/ and run the installer; in its first window tick the box "Add python.exe to PATH" before you click "Install Now".

macOS: download Python from https://www.python.org/downloads/ and run the installer. Then open the app Terminal and run this command, which installs Git and the compiler tools:

macOS (zsh):

```
xcode-select --install
```

Linux (Debian or Ubuntu; other distributions have packages of the same names): run these two commands:

Linux (bash):

```
sudo apt update
sudo apt install git python3 python3-venv
```

Then close the terminal and open a NEW one (a terminal opened before the installation does not know the new programs), and check the version of Python; it must print 3.12 or a higher number:

Windows (PowerShell):

```
py -3 --version
```

macOS (zsh) and Linux (bash):

```
python3 --version
```

If an older Linux prints a lower number (Ubuntu 22.04 has Python 3.10), install Python 3.12 with the following three commands, and in Step 3 type ‘python3.12‘ instead of ‘python3‘ in the command that creates the environment:

Linux (bash), only when the version is too low:

```
sudo add-apt-repository ppa:deadsnakes/ppa
sudo apt update
sudo apt install python3.12 python3.12-venv
```

Step 3. Get the repository and install the packages (once per computer).

The commands below download the repository (a few hundred megabytes; the folder then needs up to about 1 GB of disk space) into the folder Dirac_claude inside your home folder, create a private Python environment in the folder dirac-book-env inside your home folder (a private environment is a folder with its own copy of Python and of the packages, so that nothing else on your computer is changed), activate it (from then on the commands ‘python‘ and ‘jupyter‘ typed in this terminal are those of the environment, and the prompt starts with (dirac-book-env)), and install the packages at the pinned versions (this downloads about 90 MB and takes a few minutes; the environment takes about 400 MB of disk space). If you have done this step before, for this or for another notebook, skip it and go to Step 4; to get the newest version of the repository, run ‘git pull‘ in the repository folder after Step 4.

Windows (PowerShell):

```
cd $HOME
git clone https://github.com/once-ere/Dirac_claude.git
py -3 -m venv "$HOME\dirac-book-env"
Set-ExecutionPolicy -ExecutionPolicy RemoteSigned -Scope Process -Force
& "$HOME\dirac-book-env\Scripts\Activate.ps1"
python -m pip install --upgrade pip
python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
```

The line with ‘Set-ExecutionPolicy‘ allows PowerShell to run the activation script in this one window only; it changes nothing permanently.

macOS (zsh):

```
cd ~
git clone https://github.com/once-ere/Dirac_claude.git
python3 -m venv ~/dirac-book-env
source ~/dirac-book-env/bin/activate
python -m pip install --upgrade pip
python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
```

Linux (bash):

```
cd ~
git clone https://github.com/once-ere/Dirac_claude.git
python3 -m venv ~/dirac-book-env
source ~/dirac-book-env/bin/activate
python -m pip install --upgrade pip
python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
```

Step 4. In every new terminal: activate the environment and go into the repository folder.

Every later step starts in the repository folder with the environment active. Run these lines whenever you open a new terminal (they do no harm if the environment is already active):

Windows (PowerShell):

```
Set-ExecutionPolicy -ExecutionPolicy RemoteSigned -Scope Process -Force
& "$HOME\dirac-book-env\Scripts\Activate.ps1"
cd "$HOME\Dirac_claude"
```

macOS (zsh) and Linux (bash):

```
source ~/dirac-book-env/bin/activate
cd ~/Dirac_claude
```

Step 5. Run the notebook in JupyterLab.

In the repository folder, with the environment active, run these two lines (the first one goes into the folder of the notebooks):

Windows, macOS and Linux:

```
cd Revision/textbook/notebooks
jupyter lab 16b_staggered_grid.ipynb
```

JupyterLab opens in your web browser and shows the notebook (if no browser window opens, copy the address that starts with ‘http://localhost:8888/lab‘ from the terminal into the address bar of your browser). The name at the top right of the notebook must read Python 3 (ipykernel). Choose the menu Run > Run All Cells. While a cell runs, the label to its left shows ‘[*]‘; when it has finished, the label shows a number. The notebook has finished when the last code cell shows a number; this takes about 45 seconds on a typical laptop. Scroll to the end and compare the last printed lines with the lines in the step "What the notebook writes and what you must see" below. To keep the results, save the notebook (menu File > Save Notebook). To stop JupyterLab, choose the menu File > Shut Down, or press Ctrl+C twice in the terminal.

Step 6. Or run the notebook without a browser (headless).

In the repository folder, with the environment active, run:

Windows, macOS and Linux:

```
cd Revision/textbook/notebooks
jupyter nbconvert --to notebook --execute --inplace 16b_staggered_grid.ipynb
```

This runs every cell from the top to the bottom and saves the results into the notebook file. A failed check stops it with an error message that contains AssertionError and the name of the check. If the command ends with a line that starts with ‘[NbConvertApp] Writing‘ and shows no error, every check passed; open the notebook with ‘jupyter lab 16b_staggered_grid.ipynb‘ (in the same folder, without running the cells again) to read the printed lines and see the figures.

Step 7. What the notebook writes and what you must see.

The notebook writes (or overwrites) these files:

- ‘Revision/textbook/figures/16b.captions.json‘
- ‘Revision/textbook/figures/16b_1_staggered_grid.png‘
- ‘Revision/textbook/figures/16b_2_sturm_staircase.png‘
- ‘Revision/textbook/figures/16b_3_orbitals.png‘
- ‘Revision/textbook/figures/16b_4_matrix_heat_maps.png‘
- ‘Revision/textbook/figures/16b_5_convergence_ladder.png‘
- ‘Revision/textbook/figures/16b_6_error_ratios.png‘
- ‘Revision/textbook/figures/16b_7_brane_band_slope.png‘

It changes no other file of the repository; running it headless or saving it in JupyterLab also rewrites the notebook file itself. It does not use the internet while it runs. The files it writes are the same files that are stored in the repository (on another computer a figure may differ in a few bytes, which is harmless). To get the stored versions back, run this command in the repository folder (it also undoes every change you made yourself in the folder Revision/textbook):

Windows, macOS and Linux:

```
git checkout -- Revision/textbook
```

Every check of the notebook prints a line that starts with PASS. At the end of the notebook (the output of its last code cell) you must see exactly these lines:

```
PASS every figure file of this notebook exists
ALL 31 CHECKS PASSED (notebook 16b)
```

and the notebook must show 7 figures below the cells that draw them.

Step 8. If something goes wrong.

- "ModuleNotFoundError: No module named ..." in the notebook: JupyterLab was started without the environment. Stop it (menu File > Shut Down), do Step 4, and start it again. If the error remains, another Python installation has registered its own kernel called python3; with the environment active, run the following command and start JupyterLab again:

  ```
  python -m ipykernel install --user --name python3
  ```

- "FileNotFoundError: The repository folder was not found": the notebook was opened from a copy outside the repository. Open the file ‘Revision/textbook/notebooks/16b_staggered_grid.ipynb‘ inside the folder Dirac_claude.
- "fatal: destination path ’Dirac_claude’ already exists" in Step 3: the repository was downloaded before; skip the line with ‘git clone‘.
- Windows: "running scripts is disabled on this system": run the line with ‘Set-ExecutionPolicy‘ and then the activation line again. "py is not recognized": use ‘python‘ instead of ‘py -3‘; "python is not recognized": install Python again and tick "Add python.exe to PATH".
- Linux: "ensurepip is not available" when the environment is created: run ‘sudo apt install python3-venv‘ and repeat Step 3.
- "jupyter is not recognized" or "command not found: jupyter": the environment is not active; do Step 4. If the environment is active and the message stays, the programs

  jupyter-lab and jupyter-nbconvert are not in the folders where the terminal looks for
  programs (‘python -m jupyter‘ does not help then: it has to find the same programs).
  Start them through Python itself, in the folder of the notebook: the first command
  below does what ‘jupyter lab‘ does, the second what the headless command does:

      python -m jupyterlab 16b_staggered_grid.ipynb
      python -m nbconvert --execute --inplace 16b_staggered_grid.ipynb

- Windows: the headless run prints a RuntimeWarning that mentions the "Proactor event
  loop" and zmq: this is a message of the package pyzmq, not an error; the run continues
  normally.
- A red box with "Matplotlib is building the font cache; this may take a moment." in the
  first run after the installation: this is a message, not an error; the run continues
  and the message does not come again.
- An AssertionError names a check that failed: choose the menu Kernel > Restart Kernel
  and Run All Cells; if it fails again, install the packages again with the pip commands
  of Step 3, because a different package version can change the last digits of a result.
- The cell that computes the levels on five grids runs for a minute or longer: this is
  normal on a slow computer: the Sturm count is a loop over up to 4799 matrix rows,
  repeated about 60 times for every grid. Wait until the label shows a number.
- An AssertionError names a comparison with the record free-checks.json: the reference
  program or its record was changed. Get the stored versions back and run the notebook
  again.

      git checkout -- Revision/kohn_sham

The first code cell below (the set-up cell) repeats these instructions as comments; then it imports the packages, finds the repository folder and defines the helpers ‘save_figure‘ (saves a figure and shows it), ‘check‘ (stops with an AssertionError when a check fails, prints a PASS line when it passes), ‘report‘ (prints a key number as a RESULT line) and ‘all_checks_passed‘ (prints the last line).

In [1]:

```
# HOW TO RUN NOTEBOOK 16b (the complete instructions)
#
# STEP 1. WHAT THIS NOTEBOOK DOES AND WHAT IT NEEDS.
#
# Notebook 16b (The reference method by hand: staggered grid, Sturm counts, Richardson)
# is the file Revision/textbook/notebooks/16b_staggered_grid.ipynb of the repository
# Dirac_claude. It builds, line by line, the staggered finite-difference matrix that the
# independent reference solver uses, for the free Kohn-Sham orbital equation at zero
# 3-momentum, a problem whose levels are known exactly; it finds the levels by Sturm
# counts and bisection, shows that the grid error shrinks like the square of the cell
# width and that two Richardson steps remove it, constructs the exact discrete zero mode
# at the brane, computes the slope of the brane band at the five slices of the deflating
# history, and checks every number against the committed record of the reference solver,
# whose free-field checks it also runs again. It needs a computer with Windows 11, macOS
# or Linux, an internet connection for the installation, the program Git, and Python 3.12
# or newer (the notebooks were built with Python 3.14.5) with these packages at exactly
# these versions: numpy 2.4.6, sympy 1.14.0, mpmath 1.3.0, matplotlib 3.11.0, jupyterlab
# 4.4.10, nbformat 5.10.4, nbclient 0.10.2, ipykernel 7.1.0 and nbconvert 7.16.6. The
# notebook itself imports numpy, sympy and matplotlib; the other packages run Jupyter,
```

```
# the program that shows and runs notebooks. It does not need Rust.
#
# STEP 2. INSTALL GIT AND PYTHON (ONCE PER COMPUTER).
#
# A terminal is the window in which you type commands: on Windows the app Windows
# PowerShell (or Terminal), on macOS the app Terminal (it runs the shell zsh), on Linux
# any terminal (it runs the shell bash). Type every command of this section into a
# terminal exactly as printed, one line at a time, and press Enter after each line.
#
# Windows: download Git from https://git-scm.com/download/win and install it with the
# default choices. Download Python from https://www.python.org/downloads/ and run the
# installer; in its first window tick the box "Add python.exe to PATH" before you click
# "Install Now".
#
# macOS: download Python from https://www.python.org/downloads/ and run the installer.
# Then open the app Terminal and run this command, which installs Git and the compiler
# tools:
#
# macOS (zsh):
#     xcode-select --install
#
# Linux (Debian or Ubuntu; other distributions have packages of the same names): run
# these two commands:
#
# Linux (bash):
#     sudo apt update
#     sudo apt install git python3 python3-venv
#
# Then close the terminal and open a NEW one (a terminal opened before the installation
# does not know the new programs), and check the version of Python; it must print 3.12 or
# a higher number:
#
# Windows (PowerShell):
#     py -3 --version
#
# macOS (zsh) and Linux (bash):
#     python3 --version
#
# If an older Linux prints a lower number (Ubuntu 22.04 has Python 3.10), install Python
# 3.12 with the following three commands, and in Step 3 type python3.12 instead of
# python3 in the command that creates the environment:
#
# Linux (bash), only when the version is too low:
#     sudo add-apt-repository ppa:deadsnakes/ppa
#     sudo apt update
#     sudo apt install python3.12 python3.12-venv
#
# STEP 3. GET THE REPOSITORY AND INSTALL THE PACKAGES (ONCE PER COMPUTER).
#
# The commands below download the repository (a few hundred megabytes; the folder then
# needs up to about 1 GB of disk space) into the folder Dirac_claude inside your home
# folder, create a private Python environment in the folder dirac-book-env inside your
# home folder (a private environment is a folder with its own copy of Python and of the
# packages, so that nothing else on your computer is changed), activate it (from then on
```

```
# the commands python and jupyter typed in this terminal are those of the environment,
# and the prompt starts with (dirac-book-env)), and install the packages at the pinned
# versions (this downloads about 90 MB and takes a few minutes; the environment takes
# about 400 MB of disk space). If you have done this step before, for this or for another
# notebook, skip it and go to Step 4; to get the newest version of the repository, run
# git pull in the repository folder after Step 4.
#
# Windows (PowerShell):
#     cd $HOME
#     git clone https://github.com/once-ere/Dirac_claude.git
#     py -3 -m venv "$HOME\dirac-book-env"
#     Set-ExecutionPolicy -ExecutionPolicy RemoteSigned -Scope Process -Force
#     & "$HOME\dirac-book-env\Scripts\Activate.ps1"
#     python -m pip install --upgrade pip
#     python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
#     python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
#     python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
#
# The line with Set-ExecutionPolicy allows PowerShell to run the activation script in
# this one window only; it changes nothing permanently.
#
# macOS (zsh):
#     cd ~
#     git clone https://github.com/once-ere/Dirac_claude.git
#     python3 -m venv ~/dirac-book-env
#     source ~/dirac-book-env/bin/activate
#     python -m pip install --upgrade pip
#     python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
#     python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
#     python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
#
# Linux (bash):
#     cd ~
#     git clone https://github.com/once-ere/Dirac_claude.git
#     python3 -m venv ~/dirac-book-env
#     source ~/dirac-book-env/bin/activate
#     python -m pip install --upgrade pip
#     python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
#     python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
#     python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
#
# STEP 4. IN EVERY NEW TERMINAL: ACTIVATE THE ENVIRONMENT AND GO INTO THE REPOSITORY
# FOLDER.
#
# Every later step starts in the repository folder with the environment active. Run these
# lines whenever you open a new terminal (they do no harm if the environment is already
# active):
#
# Windows (PowerShell):
#     Set-ExecutionPolicy -ExecutionPolicy RemoteSigned -Scope Process -Force
#     & "$HOME\dirac-book-env\Scripts\Activate.ps1"
#     cd "$HOME\Dirac_claude"
#
# macOS (zsh) and Linux (bash):
```

```
#     source ~/dirac-book-env/bin/activate
#     cd ~/Dirac_claude
#
# STEP 5. RUN THE NOTEBOOK IN JUPYTERLAB.
#
# In the repository folder, with the environment active, run these two lines (the first
# one goes into the folder of the notebooks):
#
# Windows, macOS and Linux:
#     cd Revision/textbook/notebooks
#     jupyter lab 16b_staggered_grid.ipynb
#
# JupyterLab opens in your web browser and shows the notebook (if no browser window
# opens, copy the address that starts with http://localhost:8888/lab from the terminal
# into the address bar of your browser). The name at the top right of the notebook must
# read Python 3 (ipykernel). Choose the menu Run > Run All Cells. While a cell runs, the
# label to its left shows [*]; when it has finished, the label shows a number. The
# notebook has finished when the last code cell shows a number; this takes about 45
# seconds on a typical laptop. Scroll to the end and compare the last printed lines with
# the lines in the step "What the notebook writes and what you must see" below. To keep
# the results, save the notebook (menu File > Save Notebook). To stop JupyterLab, choose
# the menu File > Shut Down, or press Ctrl+C twice in the terminal.
#
# STEP 6. OR RUN THE NOTEBOOK WITHOUT A BROWSER (HEADLESS).
#
# In the repository folder, with the environment active, run:
#
# Windows, macOS and Linux:
#     cd Revision/textbook/notebooks
#     jupyter nbconvert --to notebook --execute --inplace 16b_staggered_grid.ipynb
#
# This runs every cell from the top to the bottom and saves the results into the notebook
# file. A failed check stops it with an error message that contains AssertionError and
# the name of the check. If the command ends with a line that starts with [NbConvertApp]
# Writing and shows no error, every check passed; open the notebook with jupyter lab
# 16b_staggered_grid.ipynb (in the same folder, without running the cells again) to read
# the printed lines and see the figures.
#
# STEP 7. WHAT THE NOTEBOOK WRITES AND WHAT YOU MUST SEE.
#
# The notebook writes (or overwrites) these files:
#
# - Revision/textbook/figures/16b.captions.json
# - Revision/textbook/figures/16b_1_staggered_grid.png
# - Revision/textbook/figures/16b_2_sturm_staircase.png
# - Revision/textbook/figures/16b_3_orbitals.png
# - Revision/textbook/figures/16b_4_matrix_heat_maps.png
# - Revision/textbook/figures/16b_5_convergence_ladder.png
# - Revision/textbook/figures/16b_6_error_ratios.png
# - Revision/textbook/figures/16b_7_brane_band_slope.png
#
# It changes no other file of the repository; running it headless or saving it in
# JupyterLab also rewrites the notebook file itself. It does not use the internet while
# it runs. The files it writes are the same files that are stored in the repository (on
```

```
# another computer a figure may differ in a few bytes, which is harmless). To get the
# stored versions back, run this command in the repository folder (it also undoes every
# change you made yourself in the folder Revision/textbook):
#
# Windows, macOS and Linux:
#     git checkout -- Revision/textbook
#
# Every check of the notebook prints a line that starts with PASS. At the end of the
# notebook (the output of its last code cell) you must see exactly these lines:
#
#     PASS every figure file of this notebook exists
#     ALL 31 CHECKS PASSED (notebook 16b)
#
# and the notebook must show 7 figures below the cells that draw them.
#
# STEP 8. IF SOMETHING GOES WRONG.
#
# - "ModuleNotFoundError: No module named ..." in the notebook: JupyterLab was started
#   without the environment. Stop it (menu File > Shut Down), do Step 4, and start it
#   again. If the error remains, another Python installation has registered its own
#   kernel called python3; with the environment active, run the following command and
#   start JupyterLab again:
#     python -m ipykernel install --user --name python3
# - "FileNotFoundError: The repository folder was not found": the notebook was opened
#   from a copy outside the repository. Open the file
#   Revision/textbook/notebooks/16b_staggered_grid.ipynb inside the folder Dirac_claude.
# - "fatal: destination path 'Dirac_claude' already exists" in Step 3: the repository was
#   downloaded before; skip the line with git clone.
# - Windows: "running scripts is disabled on this system": run the line with
#   Set-ExecutionPolicy and then the activation line again. "py is not recognized": use
#   python instead of py -3; "python is not recognized": install Python again and tick
#   "Add python.exe to PATH".
# - Linux: "ensurepip is not available" when the environment is created: run sudo apt
#   install python3-venv and repeat Step 3.
# - "jupyter is not recognized" or "command not found: jupyter": the environment is not
#   active; do Step 4. If the environment is active and the message stays, the programs
#   jupyter-lab and jupyter-nbconvert are not in the folders where the terminal looks for
#   programs (python -m jupyter does not help then: it has to find the same programs).
#   Start them through Python itself, in the folder of the notebook: the first command
#   below does what jupyter lab does, the second what the headless command does:
#     python -m jupyterlab 16b_staggered_grid.ipynb
#     python -m nbconvert --execute --inplace 16b_staggered_grid.ipynb
# - Windows: the headless run prints a RuntimeWarning that mentions the "Proactor event
#   loop" and zmq: this is a message of the package pyzmq, not an error; the run
#   continues normally.
# - A red box with "Matplotlib is building the font cache; this may take a moment." in
#   the first run after the installation: this is a message, not an error; the run
#   continues and the message does not come again.
# - An AssertionError names a check that failed: choose the menu Kernel > Restart Kernel
#   and Run All Cells; if it fails again, install the packages again with the pip
#   commands of Step 3, because a different package version can change the last digits of
#   a result.
# - The cell that computes the levels on five grids runs for a minute or longer: this is
#   normal on a slow computer: the Sturm count is a loop over up to 4799 matrix rows,
```

```
#   repeated about 60 times for every grid. Wait until the label shows a number.
# - An AssertionError names a comparison with the record free-checks.json: the reference
#   program or its record was changed. Get the stored versions back and run the notebook
#   again.
#     git checkout -- Revision/kohn_sham
#
# ------------------------------------------------------------------------------------------
# ==========================================================================================
# THE SET-UP (the same in every notebook of this book; it computes no physics)
# ==========================================================================================
import json  # reads and writes JSON files (text files that hold names and numbers)

## 3. The words used in this notebook

- **Orbital**: a one-particle wave function; here a pair of real functions $a(y)$,
  $b(y)$ of the hidden coordinate $y$ in $-L \le y \le 0$ ($L = 3$).
- **Level**: an allowed energy $\varepsilon$ of the orbital equation.
- **Exact** (or analytic) **value**: a number obtained by algebra, without a grid.
- **Grid**: the points that divide $-L \le y \le 0$ into $G$ equal **cells** of
  width $h = L/G$. **Nodes** are the cell ends $y_i = -L + i\,h$
  ($i = 0, \dots, G$), **half nodes** the cell centres
  $y_{p+1/2} = -L + (p + \tfrac12)\,h$ ($p = 0, \dots, G - 1$).
- **Staggered grid**: $a$ is stored at the half nodes, $b$ at the nodes.
- **Matrix** $T$: a square table of numbers; **symmetric**: $T_{rc} = T_{cr}$;
  **tridiagonal**: only the main diagonal and its two neighbours are not zero.
- **Eigenvalue** and **eigenvector**: a number $\varepsilon$ and a column $z \ne 0$
  with $T z = \varepsilon z$. A symmetric matrix of size $n$ has $n$ real
  eigenvalues.
- **Sturm count** $c(x)$: the number of eigenvalues of $T$ below a number $x$.
- **Bisection**: halving an interval that contains the wanted value until it is
  small enough.
- **Order of convergence**: the power $q$ in an error $\approx C h^q$; the reference
  has $q = 2$.
- **Richardson extrapolation**: a combination of results on several grids in which
  the leading errors cancel.
- **Machine epsilon** $\epsilon_{mach} = 2^{-52} \approx 2.2\times10^{-16}$: the
  relative size of the rounding error of one operation in the computer's numbers.
- **Parity**: the condition at the brane $y = 0$: **even** $b(0) = 0$, **odd**
  $a(0) = 0$ (the ASSUMED $Z_2$ brane). **Block type** $j = \pm 1$: the two kinds of
```

```
  $2\times 2$ blocks.
- **Zero mode**: a level with $\varepsilon = 0$ exactly.
- **Brane band**: the lowest even levels at small 3-momentum $k$, whose orbitals sit
  at the brane; its **slope** is $d\varepsilon/dk$ at $k = 0$.
```

Text cell:

```
## 4. The physical and mathematical situation

The Kohn-Sham orbitals of dirac16complex in the author's primordial field depend on
the hidden coordinate $y = \ln(\sin z)/(6H)$ (with $z = 6Hx_0$; $y = 0$ is the brane,
$y = -L$ the tip). With $\chi = (a, i\,b)$ the block equation of `ks-theory.json`
(entry `blockEquation.realForm`) reads, for the free problem ($v = 0$, constant
$M$), units $H = m = 1$:
$$a' = M a - \left(\kappa k + j\varepsilon\right) b, \qquad
b' = \left(j\varepsilon - \kappa k\right) a - M b,$$
where $' = d/dy$, $\kappa = e^{-Hy - a_{4,0}}$ and $k$ is the size of the 3-momentum.
Here $\kappa$ is one over the 3-space scale factor $e^{a_4}\sin^{1/6} z = e^{a_4 + Hy}$:
along the history $a_4$ grows, 3-space inflates, the three extra times
$x_5, x_6, x_7$ deflate with $e^{-a_4}$, and the 3-momenta are redshifted by
$e^{-a_{4,0}}$. The boundary conditions are the regular tip $b(-L) = 0$ (chosen)
and the ASSUMED $Z_2$ brane: $b(0) = 0$ for even and $a(0) = 0$ for odd orbitals.

For $k = 0$ the momentum term drops out, $\kappa$ disappears, and the levels are known
exactly. That makes this problem the reference solver's test bench: every error of
the grid can be measured against the exact answer. The interacting states of the
canonical matrix (Notebook 16a) use the same matrix with $k \ne 0$ and
self-consistent $M(y)$ and $v(y)$, where no exact answer exists.
```

Text cell:

```
## 5. The exact levels, line by line

**Even parity** ($b(-L) = 0$ and $b(0) = 0$), $k = 0$, $j^2 = 1$:

- The second equation $b' = j\varepsilon a - M b$ gives
  $a = j\,(b' + M b)/\varepsilon$ for $\varepsilon \ne 0$ (multiply by $j$ and use
  $j^2 = 1$).
- Put this $a$ into the first equation $a' = M a - j\varepsilon b$:
  $j(b'' + M b')/\varepsilon = M j (b' + M b)/\varepsilon - j\varepsilon b$.
- Multiply by $\varepsilon/j$: $b'' + M b' = M b' + M^2 b - \varepsilon^2 b$.
- Cancel $M b'$: $b'' = -(\varepsilon^2 - M^2)\,b$.
- With $p^2 = \varepsilon^2 - M^2 > 0$ the solution with $b(-L) = 0$ is
  $b = \sin(p\,(y + L))$ (a sine that starts at zero at the tip).
- $b(0) = 0$ needs $\sin(pL) = 0$, so $p = n\pi/L$ with $n = 1, 2, \dots$, and
  $\varepsilon = \pm\sqrt{M^2 + (n\pi/L)^2}$.

**The zero mode** ($\varepsilon = 0$): the equations become $a' = M a$ and
$b' = -M b$, so $a = A\,e^{My}$ and $b = B\,e^{-My}$; $b(-L) = 0$ forces $B = 0$.
So $b = 0$ everywhere and $a = A\,e^{My}$, a mode that grows towards the brane. With
$\int_{-L}^{0} a^2\,dy = 1$ we get $A^2 (1 - e^{-2ML})/(2M) = 1$, so
$A = \sqrt{2M/(1 - e^{-2ML})}$.
```

```
**Odd parity** ($b(-L) = 0$ and $a(0) = 0$): again $b = \sin(p\,(y+L))$, and then
$a = j\,(p\cos(p\,(y+L)) + M \sin(p\,(y+L)))/\varepsilon$. The condition $a(0) = 0$
is $p\cos(pL) + M\sin(pL) = 0$, that is $\tan(pL) = -p/M$, with one root $p_l$ in
each interval $((l + \tfrac12)\pi/L, (l+1)\pi/L)$, $l = 0, 1, 2, \dots$, and
$\varepsilon = \pm\sqrt{M^2 + p_l^2}$. These are the formulas of `ks-theory.json`,
entry `boundaryConditions.exactKOSpectra`.

**Odd parity has no level with $\varepsilon^2 \le M^2$**, so all its levels have
$|\varepsilon| > M$:
- $\varepsilon = 0$: as for the zero mode, $a = A\,e^{My}$ and $b = 0$; then
  $a(0) = A = 0$, so only the trivial solution $a = b = 0$ is left: no zero mode.
- $0 < \varepsilon^2 < M^2$: now $b'' = q^2 b$ with $q^2 = M^2 - \varepsilon^2 > 0$,
  and the solution with $b(-L) = 0$ is $b = \sinh(q\,(y+L))$; then
  $a(0) = j\,(q\cosh(qL) + M\sinh(qL))/\varepsilon$, which is not 0, because both
  terms in the bracket are positive.
- $\varepsilon^2 = M^2$: now $b'' = 0$, so $b = y + L$, and
  $a(0) = j\,(1 + ML)/\varepsilon$, again not 0.

**Ranks.** The levels of a sector are counted from the lowest **particle** level
(rank 0): for even parity that is the zero mode (by the convention of
`ks-theory.json`, the brane zero modes are particles), then $n = 1, 2, \dots$ are
ranks $1, 2, \dots$ and the negative levels are ranks $-1, -2, \dots$; for odd parity
rank $r \ge 0$ is $+\sqrt{M^2 + p_r^2}$ and rank $-r-1$ is its negative.

The next cell checks the two solutions with sympy (it substitutes them into both
equations and simplifies the residuals to zero) and computes the exact levels of
ranks $-3$ to $5$ for $M = 1$, $L = 3$, finding the odd roots by bisection.

## 6. The staggered grid

The reference stores $a$ at the $G$ half nodes and $b$ at the $G - 1$ inner nodes;
$b$ at the two end nodes is not stored, it is zero: $b(-L) = 0$ (tip) and, for even
parity, $b(0) = 0$ (brane). Write $u_p \approx a(y_{p+1/2})$ and
$w_i \approx b(y_i)$, so $w_0 = w_G = 0$. The unknowns are listed in the order of
$y$: $(u_0, w_1, u_1, w_2, \dots, w_{G-1}, u_{G-1})$, $2G - 1$ numbers in all. The
next cell draws this grid for $G = 6$.

## 7. From the differential equation to a matrix

The equations of section 4 at $k = 0$, written as an eigenvalue problem
$\varepsilon\,(a, b) = h\,(a, b)$, are (multiply the second by $j$ and the first by
$-j$, using $j^2 = 1$)
$$\varepsilon\,a = j\,(b' + M b), \qquad \varepsilon\,b = j\,(-a' + M a).$$
**Discretise** each at the place where its left side is stored, with centred
differences (the value halfway between two neighbours, and the difference of the two
neighbours divided by their distance $h$):

- at the half node $y_{p+1/2}$ (row of $u_p$): $b' \approx (w_{p+1} - w_p)/h$ and
  $b \approx (w_p + w_{p+1})/2$, so
  $\varepsilon\,u_p = j(-\tfrac1h + \tfrac M2)\,w_p + j(\tfrac1h + \tfrac M2)\,w_{p+1}$;
- at the node $y_i$ (row of $w_i$): $a' \approx (u_i - u_{i-1})/h$ and
  $a \approx (u_{i-1} + u_i)/2$, so
  $\varepsilon\,w_i = j(\tfrac1h + \tfrac M2)\,u_{i-1} + j(-\tfrac1h + \tfrac M2)\,u_i$.

In the order $(u_0, w_1, u_1, \dots)$ every row couples only to its two neighbours,
so the matrix $T$ is **tridiagonal**: the diagonal is zero (no $\varepsilon$-free
term at $k = 0$), and the entry between neighbours number $r$ and $r + 1$ is
$j(\tfrac1h + \tfrac M2)$ when $r$ is even (a $u$ followed by a $w$) and
$j(-\tfrac1h + \tfrac M2)$ when $r$ is odd (a $w$ followed by a $u$). The coefficient
```

```
of $w_{p+1}$ in the row of $u_p$ equals the coefficient of $u_p$ in the row of
$w_{p+1}$, and likewise for $w_p$: $T$ is **symmetric**, so its eigenvalues are real,
as the levels of a self-adjoint problem must be. Centred differences and averages
have errors of order $h^2$ with only even powers of $h$, which is what Richardson
extrapolation needs.

The next cell builds the diagonal and the off-diagonal of $T$ for even parity, prints
the whole matrix for $G = 4$, and compares the arrays for $G = 4$ and $G = 300$ with
those of the reference's own function `sector_arrays` in `ks_fd.py` (for $\lambda = 0$,
$k = 0$, even parity, $j = +1$).

## 8. Eigenvalues by counting: the Sturm count and bisection

How does one find eigenvalue number $i$ of a matrix with thousands of rows without
computing all of them? The reference counts. For a number $x$ form the **pivots**
$$q_1 = d_1 - x, \qquad q_r = d_r - x - \frac{o_{r-1}^2}{q_{r-1}}
\quad (r = 2, \dots, n).$$
They are the numbers that appear on the diagonal when $T - x\,\mathbb{1}$ is written
as $\mathcal{L} D \mathcal{L}^T$ ($\mathcal{L}$ with ones on the diagonal, $D$
diagonal; a script letter, because $L$ is the length 3), by elimination row after
row. **Sylvester's law of inertia** (a theorem of linear algebra that we quote, not
prove) says that $T - x\,\mathbb{1}$ and $D$ have the same number of negative
eigenvalues; the eigenvalues of $T - x\,\mathbb{1}$ are $\varepsilon - x$; so the
number of negative pivots is the number $c(x)$ of eigenvalues of $T$ below $x$. A
pivot that is exactly zero is replaced by a tiny negative number (as in `ks_fd`).

**Bisection** then finds eigenvalue number $i$ (counting from 0): start with an
interval $[lo, hi]$ with $c(lo) \le i < c(hi)$ (the **Gershgorin** bounds
$\min(d - |o_{left}| - |o_{right}|) - 1$ and $\max(d + \dots) + 1$ contain every
eigenvalue); take the midpoint; if $c(mid) \le i$ the eigenvalue is above $mid$,
otherwise below; keep the half that contains it; repeat until the interval is
shorter than $10^{-14}\max(1, |lo|)$. No eigenvalue can be missed or counted twice.

The next cell writes both as functions, works on many matrices or many $x$ at once
(numpy arrays), and compares the result for $G = 150$ with `numpy.linalg.eigvalsh`,
a standard routine that computes all eigenvalues of a symmetric matrix.
```

## 9. The exact discrete zero mode, and the orbitals

At $k = 0$ the grid problem has an eigenvalue that is **exactly** zero. Put
$\varepsilon = 0$ and $w_i = 0$ for every $i$: the rows of the $u$ are then
satisfied, and the row of $w_i$ demands
$(\tfrac1h + \tfrac M2)\,u_{i-1} + (-\tfrac1h + \tfrac M2)\,u_i = 0$, that is
$$u_i = q\,u_{i-1}, \qquad q = \frac{1 + Mh/2}{1 - Mh/2}.$$
So $u_p = q^p\,u_0$: a discrete exponential. Because
$\ln q = \ln(1 + Mh/2) - \ln(1 - Mh/2) = Mh + (Mh)^3/12 + \dots$, it follows the exact
zero mode $e^{My}$ up to an error of order $h^2$, and $b = 0$ exactly, as in the
continuum. A practical point: computing $q$ first and then $q^p$ multiplies the
rounding error of $q$ (about $10^{-16}$) by $p$, up to $10^{-13}$ for $p = 1200$;
computing $u_p = e^{p \ln q}$ with $\ln q$ from the two logarithms
(`numpy.log1p(x)` $= \ln(1 + x)$, accurate also for small $x$) avoids that.
```

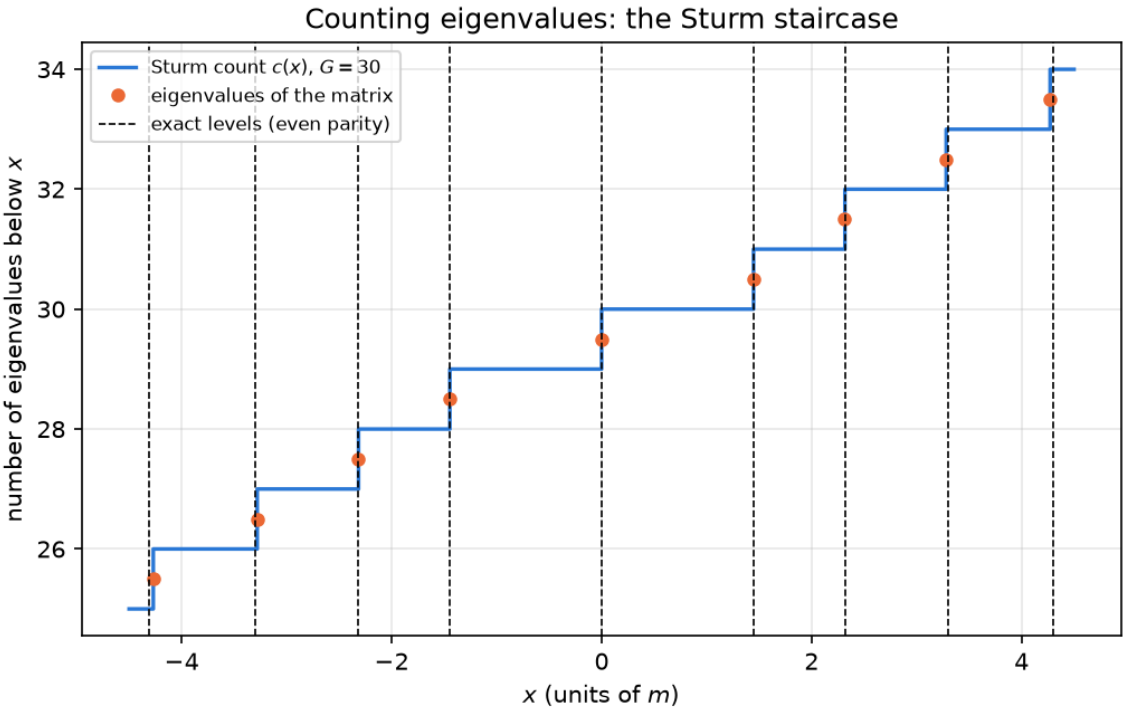

Figure 447: The Sturm count $c(x)$, the number of eigenvalues below x of the even-parity matrix with $G = 30$ cells ($M = 1$, $L = 3$, $k = 0$), against x in units of m. The count rises by one at each eigenvalue (circles, from a standard eigenvalue routine); the dashed lines are the exact levels 0 and $\pm\sqrt{1 + (n\pi/3)^2}$. Bisection finds eigenvalue number i by asking only how many eigenvalues lie below a trial value. (Notebook 16b, figure 2.)

The next cell builds the discrete zero mode for $G = 150$, checks $T z = 0$ to
rounding, and also takes from ‘numpy.linalg.eigh‘ (eigenvalues and eigenvectors) the
orbital of the even level of rank 1, $\varepsilon = \sqrt{1 + (\pi/3)^2}$. An
eigenvector z of length 1 holds $u_p\sqrt h$ and $w_i\sqrt h$, so that
$\sum (u^2 + w^2)\,h = 1$ approximates $\int (a^2 + b^2)\,dy = 1$.

In [7]:

```
def zero_mode(G, M=M_VALUE, L=L_VALUE):

```
## 10. Odd parity: the rotated frame

For odd parity the brane condition is $a(0) = 0$, but $a$ is stored at half nodes, so
no unknown sits at $y = 0$ to be set to zero. The reference therefore rotates the
two components before discretising. With the Pauli matrices
$\sigma_1, \sigma_2, \sigma_3$ and an angle $\phi(y)$ write
$\chi = e^{i\phi\sigma_1}\psi$, $\psi = (u, i\,w)$. Then:

- $e^{i\phi\sigma_1} = \cos\phi + i\sin\phi\,\sigma_1$ (because $\sigma_1^2 = 1$), so
  $a = \cos\phi\,u - \sin\phi\,w$ and $b = \sin\phi\,u + \cos\phi\,w$.
- Choose $\phi = j\,\frac{\pi}{2}\,\frac{y + L}{L}$: at the tip $\phi = 0$, so
  $b = w$ and $b(-L) = 0$ means $w(-L) = 0$; at the brane $\phi = j\pi/2$, so
  $a = -j\,w$ and $a(0) = 0$ means $w(0) = 0$. Both conditions are again "$w = 0$ at
  the ends", and the same staggered grid works.
- The equation for $\psi$ has the same form, $h' = j[-i\sigma_1\,d/dy + \phi' +
  m_2\sigma_2 + k_2\sigma_3] + v$, with $m_2 = M\cos 2\phi - K\sin 2\phi$ and
  $k_2 = M\sin 2\phi + K\cos 2\phi$ ($K = \kappa k$): the derivative of
  $e^{i\phi\sigma_1}$ gives the extra number $\phi'$, and the rotation turns
  $\sigma_2$ into $\cos 2\phi\,\sigma_2 + \sin 2\phi\,\sigma_3$ and $\sigma_3$ into
  $\cos 2\phi\,\sigma_3 - \sin 2\phi\,\sigma_2$. The next cell checks these two
  identities with sympy.
- In the matrix, $\phi' + k_2$ goes on the diagonal of the $u$ rows,
  $\phi' - k_2$ on the diagonal of the $w$ rows ($\sigma_3 = $ diag$(1, -1)$), both
  times $j$, and $M$ in the off-diagonal entries is replaced by $m_2$ (taken at the
  half node of the pair). For even parity $\phi = 0$ and everything reduces to
  section 7, with $\pm j K$ on the diagonal when $k \ne 0$.

The cell then writes the general function `sector_matrix` (both parities, any $k$
and slice $a_{4,0}$) and checks it against `ks_fd.sector_arrays` for both parities,
both block types, and $k = 0$ and $k = 0.5$.
```

## 12. The brane band along the deflating history

Now switch on a small 3-momentum $k$. The zero mode is no longer exactly at zero: it
becomes the bottom of the **brane band**, $\varepsilon \approx c\,k$ for small $k$.
How large is the slope $c = d\varepsilon/dk$ at $k = 0$?

- **Hellmann-Feynman on the matrix.** If $T(k) z = \varepsilon(k) z$ with
  $z^T z = 1$, differentiating gives $d\varepsilon/dk = z^T (dT/dk) z$ (the terms
  with $dz/dk$ cancel because $T$ is symmetric and $z^T z = 1$). For even parity
```

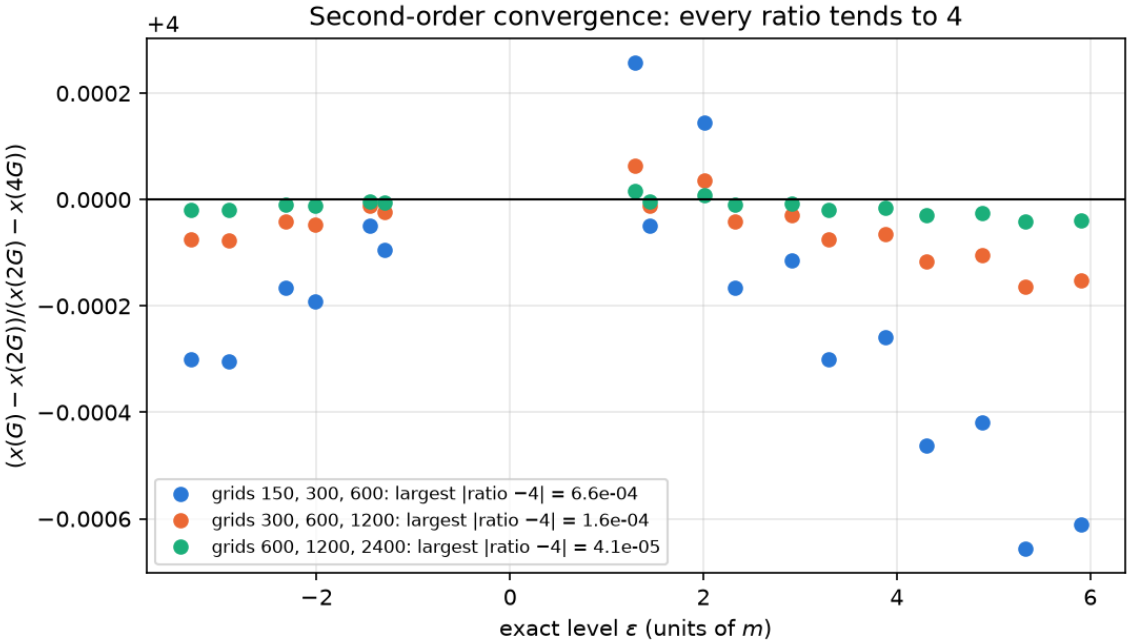

Figure 451: The convergence ratio $(x(G) - x(2G))/(x(2G) - x(4G))$ of the 17 nonzero levels of ranks -3 to 5 (both parities, $M = 1$, $L = 3$, $k = 0$) against the exact level in units of m, for three triples of grids. A ratio of 4 means an error proportional to h^2; the ratios approach 4 as the grids get finer, fastest for the low levels. The zero mode (even parity, rank 0) is exact on every grid and has no ratio. (Notebook 16b, figure 6.)

```
  and $j = +1$, $dT/dk$ is diagonal: $+\kappa(y)$ in the $u$ rows and $-\kappa(y)$ in
  the $w$ rows (from $\pm j K$, $K = \kappa k$). The zero mode has $w = 0$, so
  $c = \sum_p \kappa(y_{p+1/2})\,u_p^2\,h$.
- **In the continuum** this is $c = \int_{-L}^{0} \kappa\,a^2\,dy$ with
  $a = A e^{My}$ and $\kappa = e^{-Hy - a_{4,0}}$:
  $c = e^{-a_{4,0}} A^2 \int_{-L}^{0} e^{(2M - H)y}\,dy
  = e^{-a_{4,0}}\,\frac{2M}{1 - e^{-2ML}}\,\frac{1 - e^{-(2M - H)L}}{2M - H}$,
  the formula ‘checksNumeric.braneBandSlopeFormula‘ of ‘ks-theory.json‘.
- **The meaning.** The factor $e^{-a_{4,0}}$ is the redshift of the 3-momentum: along
  the history $a_4 = A H x_4$, 3-space inflates by $e^{a_4}$ while the three extra
  times deflate by $e^{-a_4}$ (the 7-volume stays constant), and the brane band
  flattens as $e^{-a_{4,0}}$.

The next cell computes $c$ on $G = 300, 600, 1200$ with the discrete zero mode of
section 9, extrapolates with Richardson, and compares with the formula and with the
record (entry ‘brane_band_slope‘ of ‘free-checks.json‘) at the five slices
$a_{4,0} = 0, 0.5, 1, 1.5, 2$.

all_checks_passed()
```

Out [17]:

```
PASS every figure file of this notebook exists
ALL 31 CHECKS PASSED (notebook 16b)
```

Text cell:

```
## 15. What this notebook showed

- The free orbital equation at $k = 0$ has exact levels: $0$ and
  $\pm\sqrt{M^2 + (n\pi/L)^2}$ (even), $\pm\sqrt{M^2 + p^2}$ with
  $\tan(pL) = -p/M$ (odd); sympy confirms the solutions.
- On the staggered grid the equation becomes a symmetric tridiagonal matrix, built
  here line by line; it is exactly the reference's matrix (also for odd parity in
  the rotated frame and for $k \ne 0$).
- The Sturm count gives the number of eigenvalues below any $x$, so bisection finds
  every level by its number and none can be missed.
- The discrete problem keeps an exact zero mode, $u_p = q^p u_0$, $b = 0$.
- The grid error is proportional to $h^2$ (ratios within 0.01 of 4); two Richardson
  steps bring all 18 levels to within $10^{-11}$ of the exact values, and the values
```

```
  and uncertainties reproduce the record ‘free-checks.json‘.
- The brane-band slope is $c\,e^{-a_{4,0}}$ with $c = 1.90515$ for $M = H = 1$,
  $L = 3$: the 3-momentum redshifts as 3-space inflates and the extra times deflate.
- The reference program’s own free-field job reproduces its record and passes its
  six free-field checks.
- What this does NOT show: the free problem tests the numerical method. The boundary
  conditions (the ASSUMED $Z_2$ brane, the chosen regular tip) and the model itself
  are inputs, not results, of this test.
```

16.19 Line-by-line walk-through of Notebook 16b

The notebook has 17 code cells, In [1] to In [17]; the numbers they print are in Section 16.18.

In [1], the set-up cell. It is the set-up cell of Notebook 16a, explained line by line in Section 16.12, without the two imports `shutil` and `subprocess` and without the function `rust_program`, because this notebook runs no Rust program. Its comment lines repeat the run instructions of Section 16.17, and its only other difference is the name:

```
NOTEBOOK_ID = "16b"  # this notebook: chapter 16, example b
```

In [2], the exact levels.

```
import math  # functions of single numbers (sqrt, sin, pi, ...)
import sys  # the list of folders in which Python looks for modules

import numpy as np  # arrays of numbers
import sympy as sp  # exact symbolic algebra

PALETTE = ["#2a78d6", "#eb6834", "#1baf7a", "#eda100", "#e87ba4", "#008300",
           "#4a3aa7", "#e34948"]  # the colours of the figures, in a fixed order
M_VALUE, L_VALUE = 1.0, 3.0  # the mass M = m = 1 and the tip cutoff L = 3
```

`math` holds functions of single numbers ($\sqrt{}$, sin, π, ...), `sys` the list of module folders, `numpy` arrays, and `sympy`, called `sp`, exact symbolic algebra: it computes with letters and formulas instead of numbers. `PALETTE` is the list of figure colours of Notebook 16a. The last line gives two names at once: `M_VALUE` is the mass $M = m = 1$ and `L_VALUE` the tip cutoff $L = 3$.

```
y, p, eps = sp.symbols("y p epsilon", real=True)  # real symbols
M, L = sp.symbols("M L", positive=True)  # M > 0 and L > 0 (needed by the integral)
for j_value in (1, -1):
    j = sp.Integer(j_value)
    b = sp.sin(p * (y + L))  # the even and odd solution for b
    a = j * (sp.diff(b, y) + M * b) / eps  # a from the second equation
    on_shell = {eps: sp.sqrt(M ** 2 + p ** 2)}  # epsilon^2 = M^2 + p^2
    first = sp.diff(a, y) - (M * a - j * eps * b)  # a’ - (M a - j eps b)
    second = sp.diff(b, y) - (j * eps * a - M * b)  # b’ - (j eps a - M b)
    residuals = [sp.simplify(r.subs(on_shell)) for r in (first, second)]
    check(residuals == [0, 0],
          f"sympy: b = sin(p(y+L)), a = j(b’ + M b)/eps solve both equations (j = "
          f"{j_value}) when eps^2 = M^2 + p^2")
```

`sp.symbols` creates the symbols y, p, ε (declared real) and M, L (declared positive; the integral below needs $M > 0$). For both block types ($j = 1$ and $j = -1$, made an exact sympy integer by `sp.Integer`) the cell writes the solution of Section 16.13: $b = \sin(p(y + L))$ and $a = j(b' + Mb)/\varepsilon$ (`sp.diff(b, y)` is the derivative b'). `on_shell` is a dictionary that replaces ε by $\sqrt{M^2 + p^2}$. `first` and `second` are the two equations written as "left side minus right side", which must be zero for a solution; `.subs(on_shell)` inserts ε, and `sp.simplify` brings each to its simplest form. The check requires both to be exactly 0: the formulas of Section 16.13 solve both equations whenever $\varepsilon^2 = M^2 + p^2$, for both block types (Out [2], two PASS lines).

```
zero_a = sp.exp(M * y)  # the zero mode a = e^{My}, b = 0
check(sp.simplify(sp.diff(zero_a, y) - M * zero_a) == 0,
      "sympy: a = e^(My), b = 0 solves the equations with eps = 0")
norm = sp.integrate(zero_a ** 2, (y, -L, 0))  # int_{-L}^0 e^{2My} dy
check(sp.simplify(norm - (1 - sp.exp(-2 * M * L)) / (2 * M)) == 0,
      "sympy: int e^(2My) dy over -L..0 equals (1 - e^(-2ML))/(2M)")
```

The zero mode: $a = e^{My}$ must satisfy $a' - Ma = 0$, which sympy confirms, and `sp.integrate` computes $\int_{-L}^{0} e^{2My}\,dy$ symbolically, which must equal $(1 - e^{-2ML})/(2M)$, the normalisation integral of Section 16.13.

```
def odd_root(l, M=M_VALUE, L=L_VALUE):
    """The root p_l of p cos(pL) + M sin(pL) = 0 in ((l + 1/2) pi/L, (l + 1) pi/L),
    by bisection (200 halvings: far below the rounding of a double)."""
    lo, hi = (l + 0.5) * math.pi / L, (l + 1) * math.pi / L
    f = lambda q: M * math.sin(q * L) + q * math.cos(q * L)
    f_lo = f(lo)
    for _ in range(200):
        mid = 0.5 * (lo + hi)
        if (f(mid) > 0) == (f_lo > 0):  # same sign as at lo: the root is above mid
            lo, f_lo = mid, f(mid)
        else:
            hi = mid
    return 0.5 * (lo + hi)
```

`odd_root(l)` finds the root p_l of $F(p) = M\sin(pL) + p\cos(pL)$ in the interval $((l+\frac{1}{2})\pi/L, (l+1)\pi/L)$, which Section 16.13 proved to contain exactly one root, by bisection: `f` is F written as a **lambda** (a one-line function); `f_lo` is its value at the left end; each of the 200 steps takes the midpoint and keeps the half in which F changes sign (if $F(mid)$ has the sign of $F(lo)$, the root lies above mid). Two hundred halvings shrink the interval far below the spacing of the computer's numbers, so the result is the root to the last digit.

```
RANKS = np.arange(-3, 6)  # the ranks -3, ..., 5 of the record
P_ODD = [odd_root(l) for l in range(12)]
EXACT_EVEN = np.array([0.0 if r == 0 else
                       math.copysign(math.sqrt(M_VALUE ** 2
                                               + (abs(r) * math.pi / L_VALUE) ** 2),
                                     r) for r in RANKS])
EXACT_ODD = np.array([math.sqrt(M_VALUE ** 2 + P_ODD[r] ** 2) if r >= 0 else
                      -math.sqrt(M_VALUE ** 2 + P_ODD[-r - 1] ** 2) for r in RANKS])
```

```
print("rank    even level      odd level")
for r, e, o in zip(RANKS, EXACT_EVEN, EXACT_ODD):
    print(f"{r:4d}  {e:+.12f}  {o:+.12f}")
check(all(abs(math.tan(q * L_VALUE) + q / M_VALUE) < 1e-9 for q in P_ODD),
      "the twelve odd roots satisfy tan(pL) = -p/M")
```

`RANKS` is the array of the ranks -3 to 5, `P_ODD` the first twelve odd roots. `EXACT_EVEN` holds the even levels by rank: 0 for rank 0, and $\sqrt{M^2 + (|r|\pi/L)^2}$ with the sign of the rank (`math.copysign(x, r)` gives x the sign of r). `EXACT_ODD` holds the odd levels: $+\sqrt{M^2 + p_r^2}$ for $r \geq 0$ and $-\sqrt{M^2 + p_{-r-1}^2}$ for negative ranks (rank -1 belongs to p_0). The table of Out [2] prints both with twelve decimals and a sign (`:+.12f`); for example the even level of rank 1 is $+1.447971930402$ and the odd level of rank 0 is $+1.292292828069$. The check confirms that every odd root satisfies $\tan(pL) = -p/M$ to 10^{-9}.

In [3], the staggered grid as a picture (Figure 16b.1).

```
G_SHOW = 6
h_show = L_VALUE / G_SHOW
nodes = -L_VALUE + h_show * np.arange(G_SHOW + 1)  # y_0, ..., y_G
halves = -L_VALUE + h_show * (np.arange(G_SHOW) + 0.5)  # y_{1/2}, ..., y_{G-1/2}
fig, ax = plt.subplots(figsize=(9.0, 3.0))
ax.axhline(0.0, color="k", lw=1.0)
ax.plot(halves, np.zeros(G_SHOW), "o", color=PALETTE[0], ms=10,
        label="$u_p \\approx a(y_{p+1/2})$ (half nodes)")
ax.plot(nodes[1:-1], np.zeros(G_SHOW - 1), "s", color=PALETTE[1], ms=9,
        label="$w_i \\approx b(y_i)$ (inner nodes)")
ax.plot(nodes[[0, -1]], [0.0, 0.0], "s", color=PALETTE[1], ms=9, mfc="white",
        label="$w_0 = w_G = 0$ (tip and brane, even parity)")
```

For $G = 6$ cells, `h_show` is the cell width 0.5, `nodes` the seven cell ends $y_0, \ldots, y_6$ and `halves` the six cell centres (`np.arange(n)` is the array $0, 1, \ldots, n-1$, and adding 0.5 moves to the centres). A wide, low figure is made; `axhline` draws the y axis as a horizontal line. The half nodes are drawn as blue circles (the values u_p), the inner nodes as orange squares (`nodes[1:-1]` leaves out the first and the last; the values w_i), and the two end nodes as open squares (`mfc="white"`), because there $b = 0$ is known and is not an unknown. Each label explains its marker.

ax.annotate("tip $y = -L$", (nodes[0], 0.0), (nodes[0], 0.55), ha="center")
ax.annotate("brane $y = 0$", (nodes[-1], 0.0), (nodes[-1], 0.55), ha="center")
ax.annotate("", (nodes[1], -0.75), (nodes[0], -0.75),
            arrowprops={"arrowstyle": "<->"})
ax.text(0.5 * (nodes[0] + nodes[1]), -0.95, "$h = L/G$", ha="center")
ax.set_ylim(-1.2, 0.9)
ax.set_xlim(-L_VALUE - 0.3, 0.3)
ax.set_yticks([])
ax.set_xlabel("hidden coordinate $y$")
ax.legend(fontsize=8, loc="lower center", bbox_to_anchor=(0.5, 1.0), ncol=3)
```

`annotate(text, point, text_position)` writes a text near a point: the names $u_0, \dots, u_5$ above the circles and $w_0, \dots, w_6$ below the nodes, and the words tip and brane above the two ends. An empty annotation with `arrowprops` draws a double arrow over the first cell, labelled $h = L/G$. The axes are set (no ticks on the vertical axis, `set_yticks([])`) and the legend is placed above the plot (`bbox_to_anchor` gives its position relative to the axes, `ncol=3` makes three columns).

```
save_figure(fig, "staggered_grid",
            "The staggered grid of the reference solver for $G = 6$ cells of width "
            "$h = L/G = 0.5$ on the hidden coordinate $-3 \\le y \\le 0$: the first "
            "orbital component $a$ is stored at the cell centres (circles, $u_p$), "
            "the second component $b$ at the inner cell ends (squares, $w_i$); at the "
            "tip and at the brane $b$ is zero (open squares) and is not an unknown. "
            "The $2G - 1 = 11$ unknowns alternate $u_0, w_1, u_1, \\dots, u_5$.")
```

`save_figure` saves Figure 16b.1. What the student should see: along the hidden coordinate from the tip at -3 to the brane at 0, circles and squares alternate; the $2G - 1 = 11$ unknowns are, in order, $u_0, w_1, u_1, \dots, w_5, u_5$; every circle has a square on each side, so every difference of Section 16.14 connects neighbours half a cell apart.

In [4], from the differential equation to a matrix.

```
sys.dont_write_bytecode = True  # do not write a __pycache__ folder into the record
sys.path.insert(0, str(repository_file("Revision/kohn_sham/reference")))
import ks_fd as K  # noqa: E402  the reference solver's module (Revision code)
```

As in Notebook 16a (Section 16.12, In [3]): no translated files are written into the record, the reference folder is added to the module search list, and the reference solver's module `ks_fd.py` is imported under the name `K`.

```
def even_matrix(G, j=1.0, M=M_VALUE, L=L_VALUE):
    """Diagonal d (2G - 1 numbers) and off-diagonal o (2G - 2 numbers) of T for
    even parity, k = 0, constant M."""
    h = L / G
    d = np.zeros(2 * G - 1)  # the diagonal is zero at k = 0
    r = np.arange(2 * G - 2)  # the number of the first of two neighbours
    o = np.where(r % 2 == 0, j * (1.0 / h + M / 2.0), j * (-1.0 / h + M / 2.0))
    return d, o
```

`even_matrix(G)` builds the tridiagonal matrix of Section 16.14 for even parity, $k = 0$ and constant M in its compact form: the diagonal `d` ($2G-1$ zeros, `np.zeros`) and the neighbour entries `o` ($2G-2$ numbers). `r` numbers the pairs of neighbours; `r % 2` is the remainder of r divided by 2, so `r % 2 == 0` is true for even r, and `np.where(condition, x, y)` takes $j(\frac{1}{h} + \frac{M}{2})$ where it is true and $j(-\frac{1}{h} + \frac{M}{2})$ where it is false: exactly the entries $T_{r,r+1}$ derived in Section 16.14.

```
d4, o4 = even_matrix(4)
T4 = np.diag(d4) + np.diag(o4, 1) + np.diag(o4, -1)  # the full 7 x 7 matrix
print("T for G = 4 (h = 0.75), even parity, j = +1:")
for row in T4:
    print("  " + " ".join(f"{x:+7.3f}" for x in row))
```

For $G = 4$ the full matrix is assembled: `np.diag(d4)` puts the diagonal into a square matrix, and `np.diag(o4, 1)` and `np.diag(o4, -1)` put the neighbour entries one place above and one place below it. The loop prints the 7×7 matrix row by row, each entry with sign and three decimals in seven places (`:+7.3f`); Out [4] shows the alternating entries $+1.833$ and -0.833 next to the zero diagonal.

```
for G in (4, 300):
    d, o = even_matrix(G)
    phys = K.Phys(m=M_VALUE, L=L_VALUE, H=1.0)  # the reference's parameters
    grid = K.Grid(phys, G)
    sector = K.Sectors([(0, 1, 1, 0)])  # (n2 = 0, r3 = 1, j = +1, even)
    alpha, beta = K.sector_arrays(grid, phys, sector, np.full(grid.n, M_VALUE),
                                  np.zeros(grid.n))
    check(np.array_equal(alpha[:, 0], d) and np.array_equal(beta[:, 0], o),
          f"G = {G}: our matrix equals the reference's (ks_fd.sector_arrays), "
          "entry by entry")
check(np.array_equal(T4, T4.T), "the matrix is symmetric")
```

For $G = 4$ and $G = 300$ the cell builds the same matrix with the reference's own function: `K.Phys` holds the reference's parameters ($m = 1$, $L = 3$, $H = 1$), `K.Grid` its grid, and `K.Sectors` a list of sectors, here one, ($n_2 = 0, r_3 = 1, j = +1$, even). `K.sector_arrays` returns the diagonals `alpha` and the neighbour entries `beta` of every sector's matrix (one column per sector), for the effective mass $M = 1$ at every position (`np.full(n, value)` is an array of n equal values) and the potential $v = 0$. The check requires our arrays to be **exactly** equal to the reference's (`np.array_equal`), entry by entry; the last check confirms that the 7×7 matrix equals its transpose `T4.T` (rows and columns exchanged), that is, that it is symmetric.

In [5], eigenvalues by counting: the Sturm count and bisection.

```
def sturm_count(d, o, x):
    """Number of eigenvalues below x of the tridiagonal matrix (d, o), for every
    entry of the array x."""
    x = np.asarray(x, dtype=float)
    o2 = o * o
    q = d[0] - x  # the first pivot
    q = np.where(np.abs(q) < 1e-290, -1e-290, q)  # never divide by an exact zero
    count = (q < 0).astype(int)
    for r in range(1, len(d)):
        q = d[r] - x - o2[r - 1] / q  # the next pivot
        q = np.where(np.abs(q) < 1e-290, -1e-290, q)
        count += q < 0
    return count
```

`sturm_count(d, o, x)` is the pivot recursion of Section 16.15 for every entry of the array `x` at once. `np.asarray(x, dtype=float)` makes sure `x` is an array of numbers, and `o2` holds the squares o_r^2. `q` starts as the first pivot $d_1 - x$; `np.where` replaces a pivot whose size is below 10^{-290} by -10^{-290} (never divide by an exact zero); `count` starts as 1 where the pivot is negative and 0 elsewhere (`.astype(int)` turns truth values into the numbers 1 and 0). The loop computes each next pivot $q_r = d_r - x - o_{r-1}^2/q_{r-1}$ and adds 1 to the count wherever it is negative (`count += q < 0` adds the truth values as numbers). The returned count is the number of eigenvalues below each x.

```
def bisection(d, o, index, rel_tol=1e-14):
    """Eigenvalues number index (an array of integers, 0 = the lowest) of (d, o)."""
    index = np.asarray(index)
    radius = np.zeros_like(d)
    radius[:-1] += np.abs(o)
    radius[1:] += np.abs(o)
    lo = np.full(len(index), np.min(d - radius) - 1.0)  # Gershgorin: below all
    hi = np.full(len(index), np.max(d + radius) + 1.0)  # Gershgorin: above all
    steps = 0
    while np.any(hi - lo > rel_tol * np.maximum(1.0, np.abs(lo))):
        mid = 0.5 * (lo + hi)
        above = sturm_count(d, o, mid) <= index  # True: the eigenvalue is above mid
        lo = np.where(above, mid, lo)
        hi = np.where(above, hi, mid)
        steps += 1
    return 0.5 * (lo + hi), steps
```

`bisection(d, o, index)` finds the eigenvalues with the numbers in the array `index` (0 is the lowest), all at once. `radius` is Gershgorin's radius of every row: each row gets the size of the neighbour entry on its right (`radius[:-1] += ...`, all rows but the last) and on its left (`radius[1:] += ...`, all rows but the first). `lo` and `hi` start one unit beyond Gershgorin's bounds, so every eigenvalue lies inside (Section 16.15). The `while` loop runs as long as some interval is wider than $10^{-14} \max(1, |lo|)$ (`np.any` is true if any entry is true). In each step `above` is true where at most `index` eigenvalues lie below the midpoint, that is, where the wanted eigenvalue lies at or above it; there `lo` moves up to the midpoint, elsewhere `hi` moves down. `steps` counts the halvings. The function returns the midpoints of the final intervals and the number of steps.

```
d150, o150 = even_matrix(150)
T150 = np.diag(d150) + np.diag(o150, 1) + np.diag(o150, -1)
all_eigs = np.linalg.eigvalsh(T150)  # every eigenvalue, sorted
test_x = np.linspace(-6.0, 6.0, 241) + 0.0123  # 241 test points, none at a level
counts_ok = np.array_equal(sturm_count(d150, o150, test_x),
                           np.searchsorted(all_eigs, test_x))
first_particle = int(sturm_count(d150, o150, np.array([-1e-9]))[0])
found, steps = bisection(d150, o150, first_particle + RANKS)
```

For $G = 150$ the full matrix `T150` (299×299) is assembled, and `np.linalg.eigvalsh` computes all its eigenvalues with a standard routine for symmetric matrices, sorted. `test_x` holds 241 trial values between -6 and 6, shifted by 0.0123 so that none falls on a level. `counts_ok` compares our Sturm counts with the number of eigenvalues below each trial value found by `np.searchsorted` (it tells where each `x` would be inserted into the sorted list, which is exactly that number). `first_particle` is the Sturm count at -10^{-9}, the number of eigenvalues below zero: the zero mode, the lowest particle level (rank 0), has this number. Bisection then finds the nine levels of ranks -3 to 5.

```
say(f"G = 150: {len(all_eigs)} eigenvalues; {first_particle} lie below -1e-9, so the "
    f"lowest particle level (rank 0) is eigenvalue number {first_particle}")
say(f"bisection: {steps} halvings; largest difference from eigvalsh "
    f"{np.max(np.abs(found - all_eigs[first_particle + RANKS])):.1e}")
check(counts_ok, "the Sturm count equals the number of eigvalsh eigenvalues below x "
                 "at 241 test points")
```

```
check(np.max(np.abs(found - all_eigs[first_particle + RANKS])) < 1e-12,
      "bisection with Sturm counts finds the same nine levels as eigvalsh")
```

Out [5]: 299 eigenvalues, 149 of them below -10^{-9}, so the zero mode is eigenvalue number 149; bisection needed 55 halvings (the number estimated in Section 16.15) and agrees with the standard routine to 3.8×10^{-14}. The two checks require the Sturm counts to agree at all 241 trial values and the nine bisection levels to agree with `eigvalsh` to 10^{-12}.

In [6], the Sturm staircase (Figure 16b.2).

```
d30, o30 = even_matrix(30)
xs = np.linspace(-4.5, 4.5, 3601)  # a fine set of x values
stairs = sturm_count(d30, o30, xs)
eigs30 = np.linalg.eigvalsh(np.diag(d30) + np.diag(o30, 1) + np.diag(o30, -1))
fig, ax = plt.subplots(figsize=(8.0, 4.6))
ax.step(xs, stairs, where="post", color=PALETTE[0], lw=1.6,
        label="Sturm count $c(x)$, $G = 30$")
shown = eigs30[np.abs(eigs30) < 4.5]
ax.plot(shown, np.searchsorted(eigs30, shown) + 0.5, "o", color=PALETTE[1], ms=5,
        label="eigenvalues of the matrix")
```

For a coarse grid, $G = 30$ (59 eigenvalues), `xs` holds 3601 values of x between -4.5 and 4.5, `stairs` the Sturm count at each, and `eigs30` all eigenvalues. `ax.step(..., where="post")` draws the count as a staircase whose value changes just after each x. `shown` keeps the eigenvalues inside the window (`np.abs(eigs30) < 4.5` is a mask), and each is drawn as a circle half-way up its step (`searchsorted` gives the count below it, plus 0.5).

```
exact_lines = [0.0] + [s * math.sqrt(1.0 + (n * math.pi / 3.0) ** 2)
                       for n in range(1, 5) for s in (1, -1)]
for k, e in enumerate(sorted(exact_lines)):
    ax.axvline(e, color="k", lw=0.8, ls="--",
               label="exact levels (even parity)" if k == 0 else None)
ax.set_xlabel("$x$ (units of $m$)")
ax.set_ylabel("number of eigenvalues below $x$")
ax.set_title("Counting eigenvalues: the Sturm staircase")
ax.legend(fontsize=8, loc="upper left")
save_figure(fig, "sturm_staircase",
            "The Sturm count $c(x)$, the number of eigenvalues below $x$ of the "
            "even-parity matrix with $G = 30$ cells ($M = 1$, $L = 3$, $k = 0$), "
            "against $x$ in units of $m$. The count rises by one at each eigenvalue "
            "(circles, from a standard eigenvalue routine); the dashed lines are the "
            "exact levels $0$ and $\\pm\\sqrt{1 + (n\\pi/3)^2}$. Bisection finds "
            "eigenvalue number $i$ by asking only how many eigenvalues lie below a "
            "trial value.")
```

`exact_lines` holds the exact even levels of Section 16.13 in the window: 0 and $\pm\sqrt{1 + (n\pi/3)^2}$ for $n = 1$ to 4 (a list comprehension with two `for` parts makes both signs for each n). Each is drawn as a dashed vertical line, and only the first gets a legend label (`label=... if k == 0 else None`). After the axis labels, title and legend, `save_figure` saves Figure 16b.2. What the student should see: the staircase rises by exactly one at each eigenvalue; near zero the eigenvalues of the coarse

matrix sit on the dashed exact levels (the zero mode exactly), while the outermost ones, at about ± 4.3, are visibly shifted from them, because their orbitals oscillate on the scale of a few cells and the grid error is larger.

```
check(int(sturm_count(d30, o30, np.array([4.5]))[0]
          - sturm_count(d30, o30, np.array([-4.5]))[0]) == len(shown),
      "the staircase rises by one for each eigenvalue in the window")
```

The check: the count at 4.5 minus the count at -4.5 equals the number of eigenvalues in the window.

In [7], the exact discrete zero mode and an orbital.

```
def zero_mode(G, M=M_VALUE, L=L_VALUE):
    """The exact discrete zero mode: u_p = exp(p ln q), normalised so that
    sum u^2 h = 1; returns (half nodes y, u)."""
    h = L / G
    log_q = np.log1p(M * h / 2.0) - np.log1p(-M * h / 2.0)  # ln q, accurately
    u = np.exp(np.arange(G) * log_q)
    u /= math.sqrt(np.sum(u * u) * h)
    return -L + (np.arange(G) + 0.5) * h, u
```

`zero_mode(G)` builds the discrete zero mode of Section 16.15 as $u_p = e^{p \ln q}$. `np.log1p(t)` computes $\ln(1+t)$ accurately also for small t, so `log_q` is $\ln(1 + Mh/2) - \ln(1 - Mh/2) = \ln q$ without first forming q: computing q and then q^p would multiply the rounding error of q (about 10^{-16}) by p, up to 10^{-13} for $p = 1200$. The vector is normalised so that $\sum u_p^2 h = 1$ (`u /= x` divides every entry by x), the discrete form of $\int a^2\, dy = 1$. The function returns the half nodes and the values.

```
y_half, u0 = zero_mode(150)
z = np.zeros(2 * 150 - 1)
z[0::2] = u0  # the u entries; every w entry stays 0
residual = np.max(np.abs(T150 @ z)) / np.max(np.abs(z))
A = math.sqrt(2.0 * M_VALUE / (1.0 - math.exp(-2.0 * M_VALUE * L_VALUE)))
shape_error = np.max(np.abs(u0 - A * np.exp(M_VALUE * y_half)))
say(f"discrete zero mode, G = 150: |T z| / |z| = {residual:.1e}; largest distance "
    f"from A e^(My) at the half nodes {shape_error:.2e} (A = {A:.6f})")
check(residual < 1e-12, "the discrete zero mode is an exact eigenvector with "
                        "eigenvalue 0 (to rounding), with b = 0")
check(shape_error < 1e-3, "the discrete zero mode follows A e^(My) to order h^2")
```

For $G = 150$ the zero mode is placed into a vector `z` of length 299: the u entries at the even positions (`z[0::2]` takes every second entry from the first) and zeros at the w positions. `T150 @ z` is the product of the matrix with the vector (`@` is matrix multiplication), and `residual` is its largest entry relative to the largest entry of `z`; it must vanish if z is an eigenvector with eigenvalue 0. `A` is the continuum normalisation of Section 16.13 and `shape_error` the largest distance of the grid values from $A\, e^{My}$ at the half nodes. Out [7]: residual 1.5×10^{-14} (rounding), distance 6.93×10^{-5}, $A = 1.415970$. The two checks require the residual below 10^{-12} and the distance below 10^{-3} (second order: with $h = 0.02$, $h^2 = 4 \times 10^{-4}$).

```
values, vectors = np.linalg.eigh(T150)
level = first_particle + 1  # rank 1
```

```
vec = vectors[:, level] / math.sqrt(L_VALUE / 150)  # u and w with sum (u^2+w^2) h = 1
vec *= np.sign(vec[-1])  # fix the overall sign: u at the brane positive
u1, w1 = vec[0::2], vec[1::2]
y_node = -L_VALUE + np.arange(1, 150) * (L_VALUE / 150)
p1 = math.pi / L_VALUE
e1 = math.sqrt(M_VALUE ** 2 + p1 ** 2)
b_exact = lambda yy: np.sin(p1 * (yy + L_VALUE))
a_exact = lambda yy: (p1 * np.cos(p1 * (yy + L_VALUE))
                      + M_VALUE * np.sin(p1 * (yy + L_VALUE))) / e1
norm_exact = math.sqrt(L_VALUE)  # int (a^2 + b^2) dy = L for these a and b
scale = np.sign(a_exact(np.array([y_half[-1]]))[0]) / norm_exact
```

`np.linalg.eigh` returns all eigenvalues and eigenvectors (one per column) of `T150`. `level` is the number of the level of rank 1, one above the zero mode. Its eigenvector has length 1; dividing by $\sqrt{h}$ turns it into grid values u_p, w_i with $\sum(u^2 + w^2)h = 1$, and multiplying by the sign of its last entry makes u at the brane positive (an eigenvector is fixed only up to its sign). `u1` and `w1` are its u and w entries, `y_node` the 149 inner nodes. The exact orbital of rank 1 is $b = \sin(p_1(y + L))$ and $a = (p_1 \cos(p_1(y + L)) + M \sin(p_1(y + L)))/\varepsilon_1$ with $p_1 = \pi/L$ (Section 16.13, $j = 1$); its integral $\int (a^2 + b^2)\, dy$ equals L, so `scale` divides by $\sqrt{L}$ and gives the exact orbital the sign of the grid's.

```
say(f"level of rank 1: eigenvalue {values[level]:.10f}, exact {e1:.10f}")
check(np.max(np.abs(u1 - scale * a_exact(y_half))) < 1e-3
      and np.max(np.abs(w1 - scale * b_exact(y_node))) < 1e-3,
      "the eigenvector of rank 1 follows the exact orbital (a, b) to order h^2")
```

Out [7] prints the eigenvalue 1.4479202214 next to the exact level 1.4479719304 (the grid error 5.2×10^{-5} is of order h^2), and the check requires the grid values of both components within 10^{-3} of the exact functions.

In [8], the orbitals as a picture (Figure 16b.3).

```
fig, (left, right) = plt.subplots(1, 2, figsize=(10.0, 4.0))
fine = np.linspace(-L_VALUE, 0.0, 400)
left.plot(fine, A * np.exp(M_VALUE * fine), color="k", lw=1.2,
          label="exact $a = A\\,e^{My}$")
left.plot(y_half[::5], u0[::5], "o", color=PALETTE[0], ms=5,
          label="grid $u_p$, $G = 150$")
left.axhline(0.0, color=PALETTE[1], lw=2.0, label="$b = 0$ (exactly)")
left.set_xlabel("$y$")
left.set_ylabel("orbital component")
left.set_title("zero mode, $\\varepsilon = 0$")
left.legend(fontsize=8)
```

The left panel draws the exact zero mode $A\, e^{My}$ as a black line on 400 points, the grid values u_p at every fifth half node as circles, and the line $b = 0$ in orange.

```
right.plot(fine, scale * a_exact(fine), color="k", lw=1.2, label="exact $a$")
right.plot(fine, scale * b_exact(fine), color="k", lw=1.2, ls="--",
           label="exact $b$")
right.plot(y_half[::5], u1[::5], "o", color=PALETTE[0], ms=5, label="grid $u_p$")
```

```
right.plot(y_node[::5], w1[::5], "s", color=PALETTE[1], ms=5, label="grid $w_i$")
right.set_xlabel("$y$")
right.set_title(f"rank 1, $\\varepsilon = {e1:.4f}$")
right.legend(fontsize=8)
fig.tight_layout()
```

The right panel draws the exact a (solid) and b (dashed) of rank 1 and the grid values u_p (circles) and w_i (squares), every fifth point; its title shows the level.

```
save_figure(fig, "orbitals",
            "Orbitals of the free problem at zero 3-momentum ($M = 1$, $L = 3$), "
            "normalised to $\\int (a^2 + b^2)\\,dy = 1$, against the hidden coordinate "
            "$y$ (tip $-3$, brane $0$). Left: the zero mode, $a = A e^{My}$ with "
            "$A = \\sqrt{2M/(1 - e^{-2ML})}$ and $b = 0$, localised at the brane; the "
            "circles are the exact discrete zero mode $u_p = q^p u_0$ of the grid "
            "with $G = 150$. Right: the even level of rank 1, "
            "$\\varepsilon = \\sqrt{1 + (\\pi/3)^2}$: its $b$ vanishes at the tip "
            "and at the brane, and the grid values lie on the exact curves.")
```

`save_figure` saves Figure 16b.3. What the student should see: on the left, the zero mode rises from 0.07 at the tip to 1.42 at the brane, an orbital bound to the brane, with b exactly zero; on the right, the orbital of rank 1, whose b vanishes at both ends (the even boundary conditions) while a does not; in both panels the grid points lie on the exact curves.

In [9], odd parity in the rotated frame.

```
phi = sp.symbols("phi", real=True)
s1 = sp.Matrix([[0, 1], [1, 0]])  # the Pauli matrices
s2 = sp.Matrix([[0, -sp.I], [sp.I, 0]])
s3 = sp.Matrix([[1, 0], [0, -1]])
rot = sp.cos(phi) * sp.eye(2) + sp.I * sp.sin(phi) * s1  # e^{i phi sigma1}
back = sp.cos(phi) * sp.eye(2) - sp.I * sp.sin(phi) * s1  # e^{-i phi sigma1}
ok2 = sp.simplify(back * s2 * rot - (sp.cos(2 * phi) * s2 + sp.sin(2 * phi) * s3))
ok3 = sp.simplify(back * s3 * rot - (sp.cos(2 * phi) * s3 - sp.sin(2 * phi) * s2))
check(ok2 == sp.zeros(2, 2) and ok3 == sp.zeros(2, 2),
      "sympy: the rotation turns sigma2 into cos(2 phi) sigma2 + sin(2 phi) sigma3 "
      "and sigma3 into cos(2 phi) sigma3 - sin(2 phi) sigma2")
```

The Pauli matrices are written as sympy matrices, `rot` is $R = \cos\phi + i\sin\phi\,\sigma_1$ and `back` its inverse $R^{-1} = \cos\phi - i\sin\phi\,\sigma_1$ (`sp.eye(2)` is the 2×2 unit matrix and `sp.I` the imaginary unit). `ok2` and `ok3` are $R^{-1}\sigma_2 R - (\cos 2\phi\,\sigma_2 + \sin 2\phi\,\sigma_3)$ and $R^{-1}\sigma_3 R - (\cos 2\phi\,\sigma_3 - \sin 2\phi\,\sigma_2)$, simplified; the check requires both to be the zero matrix: the two rotation rules of Section 16.14.

```
def sector_matrix(G, odd, j=1.0, k=0.0, a4=0.0, M=M_VALUE, L=L_VALUE, H=1.0):
    """Diagonal and off-diagonal of T for one sector: parity (odd True/False),
    block type j, 3-momentum k, slice a4; constant M, v = 0."""
    h = L / G
    r = np.arange(2 * G - 1)  # the position of each unknown in the list
    y_r = -L + (r + 1) * h / 2.0  # its y (half node for even r, node for odd r)
    is_u = r % 2 == 0
```

```
    K_r = np.exp(-H * y_r - a4) * k  # K = kappa k
    angle = j * 0.5 * math.pi * (y_r + L) / L if odd else np.zeros_like(y_r)
    dangle = j * math.pi / (2.0 * L) if odd else 0.0  # phi'
    m2 = M * np.cos(2 * angle) - K_r * np.sin(2 * angle)
    k2 = M * np.sin(2 * angle) + K_r * np.cos(2 * angle)
    d = np.where(is_u, j * (dangle + k2), j * (dangle - k2))
    pair = np.arange(2 * G - 2)  # the pair (r, r + 1)
    u_of_pair = np.where(pair % 2 == 0, pair, pair + 1)  # its half node
    sign = np.where(pair % 2 == 0, 1.0, -1.0)  # +1/h (u then w), -1/h (w then u)
    o = j * (sign / h + 0.5 * m2[u_of_pair])
    return d, o
```

`sector_matrix` builds the matrix of any sector, both parities, any block type j, 3-momentum k and slice $a_{4,0}$, for constant M and $v = 0$. `r` numbers the $2G-1$ unknowns and `y_r` gives each its position: the unknown number r lies at $-L + (r+1)h/2$, a half node for even r and a node for odd r; `is_u` marks the u unknowns. `K_r` is $K = \kappa k$ at each position. For odd parity `angle` is $\phi = j\,\frac{\pi}{2}\,\frac{y+L}{L}$ and `dangle` its derivative $\phi' = j\pi/(2L)$; for even parity both are zero. `m2` and `k2` are $m_2 = M\cos 2\phi - K\sin 2\phi$ and $k_2 = M\sin 2\phi + K\cos 2\phi$. The diagonal is $j(\phi' + k_2)$ in the u rows and $j(\phi' - k_2)$ in the w rows. For the neighbour entries, `pair` numbers the pairs $(r, r+1)$, `u_of_pair` is the position of the u in each pair (the first for even r, the second for odd r), and `sign` gives $+1/h$ for a u followed by a w and $-1/h$ for a w followed by a u; the entry is $j(\pm\frac{1}{h} + \frac{1}{2}m_2)$ with m_2 at the half node of the pair. These are the formulas of Section 16.14.

```
agree = []
for odd in (False, True):
    for j_value in (1.0, -1.0):
        for n2, r3, k_value in ((0, 1, 0.0), (4, 6, 0.5)):  # |k| = 0.25 sqrt(n2)
            phys = K.Phys(m=M_VALUE, L=L_VALUE, H=1.0)
            grid = K.Grid(phys, 300)
            sector = K.Sectors([(n2, r3, j_value, int(odd))])
            alpha, beta = K.sector_arrays(grid, phys, sector,
                                          np.full(grid.n, M_VALUE), np.zeros(grid.n))
            d, o = sector_matrix(300, odd, j=j_value, k=k_value)
            agree.append(max(np.max(np.abs(alpha[:, 0] - d)),
                             np.max(np.abs(beta[:, 0] - o))))
say(f"largest difference from ks_fd.sector_arrays over 8 sectors: {max(agree):.1e}")
check(max(agree) <= 1e-12,
      "sector_matrix equals the reference's matrices for both parities, both block "
      "types, k = 0 and k = 0.5")
```

The loops compare `sector_matrix` with the reference's `K.sector_arrays` for both parities (`int(odd)` is 1 for odd), both block types, and two momenta: $k = 0$ (shell $n_2 = 0$) and the shell $n_2 = 4$ with $r_3(4) = 6$ points, where $|k| = 0.25\sqrt{4} = 0.5$. `agree` collects the largest difference of each of the 8 comparisons. Out [9]: the largest is 0.0; the check requires at most 10^{-12}.

In [10], the matrices as heat maps (Figure 16b.4).

```
fig, axes = plt.subplots(1, 2, figsize=(10.0, 4.6))
for ax, odd, title in ((axes[0], False, "even parity"), (axes[1], True, "odd parity")):
    d, o = sector_matrix(8, odd)
```

```
    T = np.diag(d) + np.diag(o, 1) + np.diag(o, -1)
    image = ax.imshow(T, cmap="RdBu_r", vmin=-3.5, vmax=3.5)
    ax.set_title(f"$T$, {title}, $G = 8$")
    ax.set_xticks(range(0, 15, 2))  # whole numbers: rows and columns 0 to 14
    ax.set_yticks(range(0, 15, 2))
    ax.set_xlabel("column $c$")
    ax.set_ylabel("row $r$")
fig.colorbar(image, ax=axes, shrink=0.85, label="entry $T_{rc}$ (units of $m$)")
```

For $G = 8$ (15 unknowns, $h = 0.375$) the even and the odd matrix are assembled and drawn as **heat maps**: `imshow` paints entry T_{rc} as a coloured square in row r and column c, with the colour scale `"RdBu_r"` from blue (negative) through white (zero) to red (positive), fixed between -3.5 and 3.5 so that both panels use the same colours. The ticks are placed at the even numbers 0 to 14, and `fig.colorbar` adds one colour scale for both panels.

```
save_figure(fig, "matrix_heat_maps",
            "The reference matrices $T$ for $G = 8$ cells ($h = 0.375$, $M = 1$, "
            "$L = 3$, $j = +1$, $k = 0$) as heat maps, entry $T_{rc}$ in units of $m$ "
            "by colour (blue negative, red positive, white zero). Left, even parity: "
            "only the two neighbouring diagonals are filled, alternating "
            "$1/h + M/2 = 3.17$ and $-1/h + M/2 = -2.17$. Right, odd parity in the "
            "rotated frame: the diagonal carries $\\phi' \\pm M\\sin 2\\phi$ and the "
            "off-diagonal entries are $\\pm 1/h + \\tfrac12 M\\cos 2\\phi$, with "
            "$\\phi$ at the half node of the pair; $M\\cos 2\\phi$ goes from $+M$ at "
            "the tip to $-M$ at the brane, so the red entries fall from 3.16 to "
            "2.25 and the blue ones from -2.25 to -3.16, without a change of sign.")
```

`save_figure` saves Figure 16b.4. What the student should see: both matrices are filled only on the two diagonals next to the main diagonal (tridiagonal), and each is its own mirror image across the main diagonal (symmetric). In the even matrix the main diagonal is white (zero) and the neighbour entries alternate between red, $1/h + M/2 = 3.17$, and blue, $-1/h + M/2 = -2.17$. In the odd matrix the rotation puts $\phi' \pm M \sin 2\phi$ on the main diagonal, and the neighbour entries are $j(\pm 1/h + \frac{1}{2} m_2)$ with $m_2 = M \cos 2\phi$ (only half of m_2 enters, as in the even matrix only half of M), where ϕ is taken at the half node of the pair (`u_of_pair` in In [9]). Since m_2 goes from $+M$ at the tip to $-M$ at the brane, the entries move between the limits $1/h + M/2 = 3.17$ and $1/h - M/2 = 2.17$ (red) and $-1/h + M/2 = -2.17$ and $-1/h - M/2 = -3.17$ (blue). The half nodes do not reach the ends, so the drawn values stop a little short of these limits: with $\phi = \frac{\pi}{2} \frac{y+L}{L}$, the first red entry has $y + L = h/2$, so $\cos 2\phi = \cos(\pi/16) = 0.981$ and the entry is $2.667 + 0.490 = 3.16$; the last red entry has $y + L = 13h/2$, so $\cos 2\phi = \cos(13\pi/16) = -0.831$ and the entry is $2.667 - 0.416 = 2.25$. The blue entries run in the same way from -2.25 to -3.16. No entry changes sign, so red and blue keep alternating everywhere, but the red becomes lighter and the blue darker from the top left to the bottom right.

In [11], five grids and Richardson extrapolation.

```
GRIDS = (150, 300, 600, 1200, 2400)
EXACT = np.concatenate([EXACT_EVEN, EXACT_ODD])  # 18 levels: even, then odd
LEVELS = {}  # G -> the 18 levels on that grid
for G in GRIDS:
    found = []
```

```
    for odd in (False, True):
        d, o = sector_matrix(G, odd)
        lowest_particle = int(sturm_count(d, o, np.array([-1e-9]))[0])
        values_g, _ = bisection(d, o, lowest_particle + RANKS)
        found.append(values_g)
    LEVELS[G] = np.concatenate(found)
    say(f"G = {G:4d}: largest |level - exact| = "
        f"{np.max(np.abs(LEVELS[G] - EXACT)):.3e}")
```

`GRIDS` holds the five grids $G = 150$ to 2400 and `EXACT` the 18 exact levels (nine even, then nine odd; `np.concatenate` joins arrays). For each grid and each parity the matrix is built, the zero-mode number is found by a Sturm count at -10^{-9}, and bisection finds the nine levels of ranks -3 to 5; the 18 levels are kept in `LEVELS`, and the largest distance from the exact levels is printed. Out [11]: 2.607×10^{-3} for $G = 150$, then 6.518×10^{-4}, 1.629×10^{-4}, 4.074×10^{-5} and 1.018×10^{-5}: each halving of h divides the error by 4, as second order demands. This cell takes about ten seconds; the largest matrix has 4799 rows.

```
def richardson(x1, x2, x3):
    """Three-grid Richardson value and uncertainty, as in the reference program."""
    r_fine, r_coarse = (4.0 * x3 - x2) / 3.0, (4.0 * x2 - x1) / 3.0
    R = (16.0 * r_fine - r_coarse) / 15.0
    return R, np.abs(R - r_fine) + 2e-12 * np.maximum(1.0, np.abs(R))
```

`richardson` is the reference's three-grid extrapolation of Section 16.5, now for whole arrays at once (`np.abs` and `np.maximum` work entry by entry).

```
R18, U18 = richardson(LEVELS[300], LEVELS[600], LEVELS[1200])
record = json.loads(repository_file(
    "Revision/kohn_sham/reference/results/free-checks.json").read_text(encoding="utf-8"))
rows = [r for r in record["analytic"]["rows"]
        if float(r[0]) == 1.0 and float(r[1]) == 3.0 and r[3] == 1]
order = [(par, rank) for par in ("even", "odd") for rank in RANKS]
check([(r[2], r[4]) for r in rows] == order, "the record has our 18 rows in our order")
dev_R = max(abs(float(r[5]) - R18[i]) for i, r in enumerate(rows))
dev_U = max(abs(float(r[6]) - U18[i]) for i, r in enumerate(rows))
dev_1200 = max(abs(float(r[9]) - (LEVELS[1200][i] - EXACT[i]))
               for i, r in enumerate(rows))
say(f"against the record: R differs by at most {dev_R:.1e}, U by {dev_U:.1e}, "
    f"G = 1200 minus exact by {dev_1200:.1e}")
say(f"Richardson value minus exact: at most {np.max(np.abs(R18 - EXACT)):.1e} "
    f"(single grid G = 1200: {np.max(np.abs(LEVELS[1200] - EXACT)):.1e})")
check(dev_R < 1e-12 and dev_U < 1e-12 and dev_1200 < 1e-12,
      "our levels, R and U reproduce the 18 rows of the record",
      record="Revision/kohn_sham/reference/results/free-checks.json, analytic rows")
check(np.max(np.abs(R18 - EXACT)) <= 1e-11,
      "the Richardson values equal the exact levels to 1e-11",
      record="Revision/kohn_sham/reports/ks-reference.json, check "
             "free_k0_analytic_spectra")
```

`R18` and `U18` are the Richardson values and uncertainties of the 18 levels from $G = 300$, 600, 1200. `record` is the committed file `free-checks.json`; `rows` keeps its rows with $m = 1$, $L = 3$ and $j = +1$

(each row lists m, L, parity, j, rank, R, U, the exact level, R minus exact, and the $G = 1200$ value minus exact). The first check confirms that these are our 18 rows in our order (`order` lists the pairs (parity, rank)). `dev_R`, `dev_U` and `dev_1200` are the largest differences between the record and our R, our U and our $G = 1200$ errors. Out [11]: 8.9×10^{-15}, 1.3×10^{-15} and 6.2×10^{-15}, so the second check (all below 10^{-12}) reproduces the record. The Richardson values lie within 1.2×10^{-14} of the exact levels, while the best single grid $G = 1200$ is 4.1×10^{-5} away: two Richardson steps gain about nine digits. The third check requires 10^{-11}, the criterion of the reference's check `free_k0_analytic_spectra`.

In [12], the Richardson ladder (Figure 16b.5).

```
hs = np.array([L_VALUE / G for G in GRIDS])
picks = [("even", 1), ("odd", 0), ("even", 5)]
fig, ax = plt.subplots(figsize=(8.0, 6.4))
for colour, (par, rank) in zip(PALETTE, picks):
    i = order.index((par, rank))
    single = np.array([abs(LEVELS[G][i] - EXACT[i]) for G in GRIDS])
    one = np.array([abs((4.0 * LEVELS[GRIDS[g + 1]][i] - LEVELS[GRIDS[g]][i]) / 3.0
                        - EXACT[i]) for g in range(4)])
    two = np.array([abs(richardson(LEVELS[GRIDS[g]][i], LEVELS[GRIDS[g + 1]][i],
                                   LEVELS[GRIDS[g + 2]][i])[0] - EXACT[i])
                    for g in range(3)])
    label = f"{par} rank {rank} ($\\varepsilon = {EXACT[i]:.3f}$)"
    ax.loglog(hs, single, "o-", color=colour, lw=1.4, label=f"{label}: single grid")
    ax.loglog(hs[:4], one, "s--", color=colour, lw=1.2, label="one step")
    ax.loglog(hs[:3], np.maximum(two, 1e-16), "^:", color=colour, lw=1.2,
              label="two steps")
```

`hs` holds the five cell widths. For three levels (even rank 1, odd rank 0 and even rank 5; `order.index` finds a level's position), the cell computes three error series against the exact level: `single`, the five single grids; `one`, the four one-step values $(4x(h/2) - x(h))/3$ of neighbouring pairs; and `two`, the three three-grid values of neighbouring triples. Each series is drawn on logarithmic axes in the level's colour: circles with solid lines, squares with dashed lines, triangles with dotted lines (`"^:"`); zero errors are raised to 10^{-16}.

```
ax.axhline(1e-14, color="k", lw=0.8, ls="-.", label="rounding floor $10^{-14}$")
ax.set_xlabel("cell width $h$ of the coarsest grid used (units of $1/H$)")
ax.set_ylabel("distance from the exact level (units of $m$)")
ax.set_title("The Richardson ladder: slopes 2, 4 and then rounding")
ax.set_ylim(1e-16, 1e-1)
ax.xaxis.set_minor_formatter(matplotlib.ticker.NullFormatter())
ax.set_xticks(hs)  # tick labels only at the five cell widths
ax.set_xticklabels([f"{t:g}" for t in hs])
ax.legend(fontsize=7, ncol=3, loc="upper center", bbox_to_anchor=(0.5, -0.13))
```

The dash-dotted line at 10^{-14} marks the rounding floor. The axes, the tick labels at the five cell widths (as in Notebook 16a, In [8]) and a legend in three columns below the plot (`bbox_to_anchor=(0.5, -0.13)` places it under the axes) complete the figure.

```
save_figure(fig, "convergence_ladder",
            "Distance of the computed level from the exact level, in units of $m$, "
```

```
            "against the cell width $h = 3/G$ for $G = 150$ to $2400$, logarithmic "
            "axes, for three levels of the free problem: circles, single grids "
            "(slope 2, error proportional to $h^2$); squares, one Richardson step "
            "$(4x(h/2) - x(h))/3$ (slope 4); triangles, the three-grid value of the "
            "reference (two steps), at the rounding floor near $10^{-14}$ on the "
            "coarsest triple for the two lower levels and from the second triple on "
            "for rank 5. "
            "The high level of rank 5 has the largest errors, because its orbital "
            "varies fastest from cell to cell.")
```

`save_figure` saves Figure 16b.5. What the student should see: the single-grid errors fall along straight lines of slope 2 (a factor 4 per halving), the one-step errors along lines of slope 4 (a factor 16), and the two-step errors reach the rounding floor of about 10^{-14} at once, for the two lower levels already on the coarsest triple and for the level of rank 5 from the second triple on; there they scatter instead of falling further, because at the floor rounding, not the grid, sets the error. The high level of rank 5 has the largest errors in every series, because its orbital varies fastest from cell to cell.

In [13], every ratio tends to 4 (Figure 16b.6).

```
fig, ax = plt.subplots(figsize=(8.0, 4.4))
worst = {}
for colour, (g1, g2, g3) in zip(PALETTE, ((150, 300, 600), (300, 600, 1200),
                                          (600, 1200, 2400))):
    d1, d2 = LEVELS[g1] - LEVELS[g2], LEVELS[g2] - LEVELS[g3]
    keep = (np.abs(d1) > 1e-10) & (np.abs(d2) > 1e-10)  # not the zero mode
    ratio = d1[keep] / d2[keep]
    worst[(g1, g2, g3)] = float(np.max(np.abs(ratio - 4.0)))
    ax.plot(EXACT[keep], ratio, "o", color=colour, ms=6,
            label=f"grids {g1}, {g2}, {g3}: largest $|$ratio $- 4|$ = "
                  f"{worst[(g1, g2, g3)]:.1e}")
ax.axhline(4.0, color="k", lw=1.0)
ax.set_xlabel("exact level $\\varepsilon$ (units of $m$)")
ax.set_ylabel("$(x(G) - x(2G))/(x(2G) - x(4G))$")
ax.set_title("Second-order convergence: every ratio tends to 4")
ax.legend(fontsize=8)
```

For three triples of grids the convergence ratio of Section 16.4 is computed for all 18 levels; `keep` leaves out the one level whose differences are below 10^{-10}, the zero mode (even parity, rank 0), which is exact on every grid, so 17 ratios remain per triple (the odd parity has no zero mode: its rank 0 is the bulk edge 1.2923). `worst` keeps each triple's largest distance from 4, and the ratios are drawn against the exact level energies, one colour per triple, with the line 4.

```
save_figure(fig, "error_ratios",
            "The convergence ratio $(x(G) - x(2G))/(x(2G) - x(4G))$ of the 17 nonzero "
            "levels of ranks $-3$ to $5$ (both parities, $M = 1$, $L = 3$, $k = 0$) "
            "against the exact level in units of $m$, for three triples of grids. A "
            "ratio of 4 means an error proportional to $h^2$; the ratios approach 4 "
            "as the grids get finer, fastest for the low levels. The zero mode (even "
            "parity, rank 0) is exact on every grid and has no ratio.")
say("largest |ratio - 4| per triple: " + ", ".join(
    f"{k}: {v:.2e}" for k, v in worst.items()))
```

```
check(worst[(300, 600, 1200)] <= 0.01
      and worst[(600, 1200, 2400)] < worst[(300, 600, 1200)]
      and int(np.sum(keep)) == 17,  # 18 levels minus the one zero mode
      "the ratios lie within 0.01 of 4 and approach 4 on finer grids",
      record="Revision/kohn_sham/reports/ks-reference.json, check "
             "free_convergence_order_two")
```

`save_figure` saves Figure 16b.6, and the printed line (Out [13]) gives the largest distances from 4: 6.57×10^{-4}, 1.64×10^{-4} and 4.10×10^{-5} for the triples $(150, 300, 600)$, $(300, 600, 1200)$ and $(600, 1200, 2400)$, each four times smaller than the one before, as the correction $\frac{15}{16}\frac{d}{c}h^2$ of Section 16.4 predicts. What the student should see: the 17 ratios of each triple lie close to 4, the finer triples closer, and the high levels deviate most. The check requires the middle triple within 0.01 of 4 (the reference's criterion `free_convergence_order_two` asks for $[3.99, 4.01]$), the finest triple closer still, and exactly 17 kept levels (`np.sum(keep)` counts the true entries of the mask of the last triple; `int` makes it a whole number), so that only the zero mode was left out.

In [14], the brane band along the deflating history.

```
SLICES = (0.0, 0.5, 1.0, 1.5, 2.0)

def slope_formula(a4, M=M_VALUE, H=1.0, L=L_VALUE):
    """c = e^(-a4) (2M/(1 - e^(-2ML))) (1 - e^(-(2M - H)L))/(2M - H)."""
    return (math.exp(-a4) * 2.0 * M / (1.0 - math.exp(-2.0 * M * L))
            * (1.0 - math.exp(-(2.0 * M - H) * L)) / (2.0 * M - H))
```

`SLICES` are the five slices $a_{4,0} = 0, 0.5, 1, 1.5, 2$, and `slope_formula` is the slope $c(a_{4,0})$ derived in Section 16.15.

```
per_grid = {}
for G in (300, 600, 1200):
    yh, u = zero_mode(G)
    weight = u * u * (L_VALUE / G)  # u_p^2 h, summing to 1
    per_grid[G] = np.array([np.sum(np.exp(-yh - a4) * weight) for a4 in SLICES])
R_slope, U_slope = richardson(per_grid[300], per_grid[600], per_grid[1200])
```

For the grids 300, 600, 1200 the discrete zero mode is built; `weight` holds $u_p^2 h$, which adds up to 1; and the slope at each slice is $\sum \kappa(y_{p+1/2})\, u_p^2\, h$ with $\kappa = e^{-y-a_{4,0}}$ ($H = 1$), the discrete Hellmann-Feynman formula of Section 16.15. Richardson extrapolation over the three grids gives `R_slope`.

```
formula = np.array([slope_formula(a4) for a4 in SLICES])
theory = json.loads(repository_file("Revision/kohn_sham/ks-theory.json").read_text(
    encoding="utf-8"))
stated = float(theory["checksNumeric"]["braneBandSlope_M1_H1_L3_a0"])
rec_rows = record["brane_band_slope"]["rows"]
print("a4,0   slope (grid, Richardson)   formula            record")
for i, a4 in enumerate(SLICES):
    print(f"{a4:4.1f}   {R_slope[i]:.15f}      {formula[i]:.15f}  "
          f"{float(rec_rows[i][1]):.15f}")
```

`formula` holds the exact slopes. `theory` is the committed theory file `ks-theory.json`, and `stated` its number `checksNumeric.braneBandSlope_M1_H1_L3_a0`, the slope at $a_{4,0} = 0$ written in the file. `rec_rows` are the rows of the record's entry brane_band_slope. The table of Out [14] prints, for each slice, the grid value, the formula and the record with fifteen decimals; at $a_{4,0} = 0$ the three agree to fourteen decimals, 1.90514825364486, and at $a_{4,0} = 2$ all three read 0.257833778514766.

```
rel_formula = np.max(np.abs(R_slope - formula) / formula)
rel_record = max(abs(float(r[1]) - R_slope[i]) / formula[i]
                 for i, r in enumerate(rec_rows))
say(f"largest relative difference: from the formula {rel_formula:.1e}, from the "
    f"record {rel_record:.1e}")
print("stated in ks-theory.json (checksNumeric): c at a4,0 = 0 is "
      + theory["checksNumeric"]["braneBandSlope_M1_H1_L3_a0"])
check(rel_formula <= 1e-11 and abs(slope_formula(0.0) - stated) <= 1e-15 * stated,
      "the grid slope equals c e^(-a4,0) of ks-theory.json at the five slices",
      record="Revision/kohn_sham/reports/ks-reference.json, check "
             "free_brane_band_slope")
check(rel_record <= 1e-13, "our slopes reproduce the record's brane_band_slope rows",
      record="Revision/kohn_sham/reference/results/free-checks.json, brane_band_slope")
check(np.allclose(R_slope[1:] / R_slope[:-1], math.exp(-0.5), rtol=1e-12, atol=0),
      "from slice to slice the slope shrinks by exactly e^(-0.5)")
```

`rel_formula` and `rel_record` are the largest relative differences from the formula and from the record: 3.8×10^{-16} and 2.6×10^{-15} (Out [14]). The line printed next shows the number written in `ks-theory.json`. The first check requires the grid slope to equal the formula to 10^{-11} and the formula at $a_{4,0} = 0$ to equal the stated number to 10^{-15}, the reference's criterion `free_bra ne_band_slope`; the second reproduces the record's rows; the third confirms that from slice to slice the slope shrinks by exactly $e^{-0.5}$ (`np.allclose` with a relative tolerance 10^{-12}; `R_slope[1:] / R_slope[:-1]` divides each slope by the one before).

In [15], the brane band as a picture (Figure 16b.7).

```
fig, (left, right) = plt.subplots(1, 2, figsize=(10.0, 4.2))
a_fine = np.linspace(0.0, 2.0, 100)
left.semilogy(a_fine, [slope_formula(a) for a in a_fine], color="k", lw=1.2,
              label="formula $c\\,e^{-a_{4,0}}$")
left.semilogy(SLICES, R_slope, "o", color=PALETTE[0], ms=8,
              label="grid, three-grid Richardson value")
left.set_xlabel("slice $a_{4,0}$ (3-space inflates, extra times deflate)")
left.set_ylabel("brane-band slope $d\\varepsilon/dk$ at $k = 0$")
left.set_title("The brane band flattens as $e^{-a_{4,0}}$")
left.legend(fontsize=8)
```

The left panel draws the formula $c\,e^{-a_{4,0}}$ on 100 slices as a black line and the five Richardson values as circles, on a logarithmic vertical axis, where a function e^{-a} is a straight line.

```
hs3 = np.array([L_VALUE / G for G in (300, 600, 1200)])
right.loglog(hs3, [abs(per_grid[G][0] - formula[0]) for G in (300, 600, 1200)],
             "o-", color=PALETTE[1], lw=1.5, ms=7,
             label="single grid, $a_{4,0} = 0$")
```

```
right.loglog(hs3, abs(per_grid[300][0] - formula[0]) / 3.0 * (hs3 / hs3[0]) ** 2,
             "k--", lw=0.9, label="slope 2 (drawn a factor 3 lower)")
right.xaxis.set_minor_formatter(matplotlib.ticker.NullFormatter())
right.set_xticks(hs3)  # tick labels only at the three cell widths
right.set_xticklabels([f"{t:g}" for t in hs3])
right.set_xlabel("cell width $h$")
right.set_ylabel("$|c(G) - c|$")
right.set_title("grid error of the slope")
right.legend(fontsize=8)
fig.tight_layout()
```

The right panel draws, for $a_{4,0} = 0$, the distance of the single-grid slopes from the exact slope against the cell width, with a dashed line of slope 2 drawn a factor 3 lower, and tick labels at the three cell widths.

```
save_figure(fig, "brane_band_slope",
            "The slope $d\\varepsilon/dk$ at $k = 0$ of the brane band (even parity, "
            "$j = +1$, $M = H = 1$, $L = 3$). Left: against the slice $a_{4,0}$ of the "
            "history, logarithmic vertical axis; the Richardson values of the grid "
            "(circles) lie on the formula of ks-theory.json, $c(0)\\,e^{-a_{4,0}}$ "
            "with $c(0) = 1.90515$: the 3-momentum is redshifted as 3-space inflates "
            "while the three extra times deflate. Right: the single-grid values at "
            "$a_{4,0} = 0$ approach the exact slope with an error proportional to "
            "$h^2$ (parallel to the dashed line of slope 2).")
```

`save_figure` saves Figure 16b.7. What the student should see: on the left, the five circles lie exactly on a straight line falling by a factor $e^{-2} = 0.135$ from 1.905 to 0.258: the brane band flattens as 3-space inflates and the extra times deflate, because the 3-momentum is redshifted; on the right, the grid error of the slope falls with slope 2, from about 1.3×10^{-5} to 8×10^{-7}.

In [16], the reference program's own free-field job.

```
import run_reference as RR  # noqa: E402  the reference program (Revision code)

CO = RR.theory_coefficients()  # coefficients read and checked from ks-theory.json
free = RR.jsonable(RR.free_checks_job(CO)["data"])
committed = repository_file(
    "Revision/kohn_sham/reference/results/free-checks.json").read_text(encoding="utf-8")
text = json.dumps(free, indent=1, ensure_ascii=True) + "\n"  # as the program writes
say(f"the new free-field result is identical to the record byte for byte: "
    f"{text == committed}")
```

The reference program is imported (as in Notebook 16a), and its job `free_checks_job` is run: it computes the exact-level comparison for three choices of (M, L), both block types and both parities on five grids, the zero mode, the brane-band slope and the split of every sector into particle and sea levels (about ten seconds). Its result is written as text exactly as the program writes the file and compared with the committed file; Out [16] says that the two are identical byte for byte.

```
same = json.loads(text) == json.loads(committed)
if not same:  # another computer may round the last digits differently
```

```
    old = json.loads(committed)["analytic"]
    same = all(abs(float(a[5]) - float(b[5])) < 1e-12
               for a, b in zip(free["analytic"]["rows"], old["rows"]))
check(same, "the reference's free-field job reproduces free-checks.json",
      record="Revision/kohn_sham/reference/results/free-checks.json")
```

If the texts were not identical (another computer may round the last digits differently), `same` would still accept the result when the decoded contents are equal or the Richardson values of all rows agree to 10^{-12}. The check requires this.

```
an, zm = free["analytic"], free["zero_mode"]
bb, pb = free["brane_band_slope"], free["particle_branch"]
criteria = {
    "free_k0_analytic_spectra": an["max_error_richardson"] <= 1e-11,
    "free_convergence_order_two": 3.99 <= an["ratio_min"] and an["ratio_max"] <= 4.01,
    "free_k0_block_type_symmetry": an["jsym_max"] <= 1e-13
    and zm["jsym_profile"] <= 1e-13,
    "free_zero_mode": zm["max_abs_eps"] <= 1e-13 and zm["max_w_over_u"] <= 1e-12
    and zm["profile_richardson_max_error"] <= 1e-9,
    "free_brane_band_slope": bb["max_rel"] <= 1e-11
    and bb["formula_vs_theory_number"] <= 1e-15,
    "free_particle_branch": pb["violations"] == 0
    and pb["closest_to_zero_away_from_zero_modes"] > 1e-3,
}
```

`an`, `zm`, `bb` and `pb` are the four parts of the result. `criteria` is a dictionary from the names of the six free-field checks of the reference report to their conditions, with exactly the thresholds of the reference program: the Richardson levels within 10^{-11} of the exact ones; all convergence ratios in $[3.99, 4.01]$; the two block types' spectra and zero-mode profiles equal to 10^{-13}; the zero mode's eigenvalue below 10^{-13}, its w entries below 10^{-12} of its u entries and its extrapolated profile within 10^{-9} of $A\,e^{My}$; the slope within 10^{-11} (relative) of the formula, and the formula equal to the stated number; and no level on the wrong side of zero, with no level within 10^{-3} of zero apart from the zero modes.

```
say(f"max error of the Richardson values {an['max_error_richardson']:.1e}; ratios "
    f"{an['ratio_min']:.5f} to {an['ratio_max']:.5f}; zero mode |eps| <= "
    f"{zm['max_abs_eps']:.1e}; slope {bb['max_rel']:.1e} relative")
report = json.loads(repository_file(
    "Revision/kohn_sham/reports/ks-reference.json").read_text(encoding="utf-8"))
verdicts = {c["name"]: c["verdict"] for c in report["checks"]}
for name, ok in criteria.items():
    check(ok and verdicts[name] == "PASS", f"{name} holds for the new run",
          record=f"Revision/kohn_sham/reports/ks-reference.json, check {name}")
```

The printed line (Out [16]) gives the largest error of the Richardson levels (2.8×10^{-14}, over all three (M, L)), the range of the ratios (3.99977 to 4.00019), the size of the zero mode's eigenvalue (1.3×10^{-39}) and the slope's relative error (2.6×10^{-15}); these are the numbers of the reference report. The report's verdicts are read into a dictionary, and the loop makes one check per criterion: it must hold for the new run and the report's verdict must be PASS. Six PASS lines follow, each naming the check of `Revision/kohn_sham/reports/ks-reference.json` that it reproduces.

In [17], the last check.

```
figure_files = [f"{FIGURE_FOLDER}/16b_{k}_{name}.png" for k, name in enumerate(
    ["staggered_grid", "sturm_staircase", "orbitals", "matrix_heat_maps",
     "convergence_ladder", "error_ratios", "brane_band_slope"], start=1)]
check(all(output_file(f).is_file() for f in figure_files),
      "every figure file of this notebook exists")
all_checks_passed()
```

As In [23] of Notebook 16a, for the seven figures; it prints ALL 31 CHECKS PASSED (notebook 16b): five checks in In [2], three each in In [4], In [7], In [11] and In [14], two each in In [5] and In [9], seven in In [16], and one each in In [6], In [13] and In [17].

16.20 How the cross-check caught a rounding error: the chemical potential

What happened. The first cross-check of the record compared a representative subset of the canonical matrix (18 of the 75 ground states and 8 of the 135 thermal states). It failed one check, `thermo_state_functions`, in one state, N8_lamm1_a00_T10: the Rust solver gave the chemical potential $\mu = 0.2100104489071649$ and the reference 0.2100104497343054, a difference of 8.27×10^{-10} against a tolerance of 7.97×10^{-12}, a ratio of about 104 (`Revision/kohn_sham/checker/README.md`, History 1). The tolerance was not widened. Instead the cause was found: the levels of both solvers were right, and the Rust solver's computation of μ from them was wrong in the tenth decimal, because of the way ordinary computer numbers round. This section explains every step of that diagnosis; Notebook 16c repeats it with numbers it computes itself.

The Mermin condition and its slope, line by line. At a temperature $T > 0$ the occupation of a level ε_i is the Fermi-Dirac number $f(x_i)$ with $x_i = (\varepsilon_i - \mu)/T$ and $f(x) = 1/(1 + e^x)$, and each level holds g_i states (its **degeneracy**; in this model $g = 4r_3(n_2)$, Chapter 15). The chemical potential is the root of the **Mermin condition**

$$N(\mu) = \sum_i g_i \, f\Big(\frac{\varepsilon_i - \mu}{T}\Big) = N.$$

How fast does $N(\mu)$ change with μ?

$$f'(x) = -\frac{e^x}{(1 + e^x)^2}.$$

Rule: $f = (1 + e^x)^{-1}$ and the chain rule: the derivative of u^{-1} is $-u^{-2}u'$, with $u' = e^x$.

$$\frac{e^x}{(1 + e^x)^2} = \frac{1}{1 + e^x} \cdot \frac{e^x}{1 + e^x} = f(x)\,(1 - f(x)).$$

Rule: split the fraction, and $1 - f = \frac{1+e^x-1}{1+e^x} = \frac{e^x}{1+e^x}$.

$$\frac{dN}{d\mu} = \sum_i g_i \, f'(x_i) \, \frac{dx_i}{d\mu} = \frac{1}{T} \sum_i g_i \, f(x_i)\,(1 - f(x_i)).$$

Rule: the chain rule with $dx_i/d\mu = -1/T$, and $f' = -f(1-f)$. Every term is positive, so $N(\mu)$ increases with μ and has at most one root. As μ goes to $-\infty$ every f tends to 0, and as μ goes to $+\infty$ every f tends to 1, so if the levels hold more than N states the root exists (intermediate value theorem). We write $N' = dN/d\mu$.

The activated regime, line by line. In N8_lamm1_a00_T10 the eight quanta exactly fill the two lowest levels, $\varepsilon_0 = 0.000245562708$ (two levels of 4 states each, $g_0 = 8$ together); the next level is $\varepsilon_1 = 0.430761462627$ with $g_1 = 24$ states (Notebook 16c, Out [2]). The **gap** between them, 0.4305, is 43 times the temperature $T = 0.01$. When a gap is many times T the state is in the **activated regime**: only very few quanta are thermally lifted across it. Write H_{th} for the **thermal holes** (the subscript th, for thermal, keeps them apart from the author's constant H), the missing quanta below μ, and P for the **thermal particles** above it:

$$H_{th} = g_0\,(1 - f(x_0)) = \frac{g_0}{1 + e^{(\mu-\varepsilon_0)/T}} \approx g_0\, e^{-(\mu-\varepsilon_0)/T}, \qquad P = g_1\, f(x_1) \approx g_1\, e^{-(\varepsilon_1-\mu)/T}.$$

Rule: $1 - f(x) = 1/(1 + e^{-x})$, and $1/(1 + e^s) \approx e^{-s}$ when s is large (here $s \approx 21$, so the error is a relative $e^{-21} \approx 10^{-9}$). Since $g_0 = N$, the Mermin condition $g_0(1 - H_{th}/g_0) + P = N$ says simply $P = H_{th}$: as many quanta above the gap as are missing below it. Taking logarithms of $g_0\, e^{-(\mu-\varepsilon_0)/T} = g_1\, e^{-(\varepsilon_1-\mu)/T}$:

$$\ln g_0 - \frac{\mu - \varepsilon_0}{T} = \ln g_1 - \frac{\varepsilon_1 - \mu}{T} \quad \Longrightarrow \quad \mu = \frac{\varepsilon_0 + \varepsilon_1}{2} - \frac{T}{2}\,\ln\frac{g_1}{g_0}.$$

Rule: $\ln(ge^{-s}) = \ln g - s$; collect the terms with μ ($2\mu/T$ on one side) and solve. With the numbers, $(\varepsilon_0 + \varepsilon_1)/2 = 0.215503513$ and $\frac{T}{2}\ln 3 = 0.005493061$, so $\mu \approx 0.210010451$: μ sits near the middle of the gap, shifted a little towards the lower level because the upper level has three times more states. (This simple estimate is within 1.5×10^{-9} of the exact root; Exercise 7 finds the small correction.) Then

$$N' = \frac{1}{T}\sum_i g_i f_i (1 - f_i) \approx \frac{H_{th} + P}{T} = \frac{2H_{th}}{T} = \frac{2 \cdot 6.21 \times 10^{-9}}{0.01} = 1.24 \times 10^{-6}.$$

Rule: for a full level $f(1-f) \approx 1 - f$, for an empty level $f(1-f) \approx f$; then $P = H_{th}$, and $H_{th} = 6.21 \times 10^{-9}$ (Notebook 16c, Out [3]). So $N(\mu)$ is extremely flat: moving μ by 10^{-9} changes $N(\mu)$ by only 1.2×10^{-15}. Conversely, an error δ in a computed value of $N(\mu) - N$ moves the computed root by δ/N', about 8×10^5 times δ (the root of the tangent line moves by the error divided by the slope). The problem is **ill-conditioned**: its answer reacts strongly to small errors of its input.

Numbers in a computer. A **double**, the ordinary number of a computer, is stored as a sign, 53 binary digits and an exponent (the IEEE 754 standard). Between two neighbouring powers of two, $2^k \le x < 2^{k+1}$, the doubles are equally spaced, 2^{k-52} apart. Between 1 and 2 the spacing is $2^{-52} = 2.2 \times 10^{-16}$, the **machine epsilon** ϵ_{mach}; between 4 and 8 it is $2^{-50} = 8.9 \times 10^{-16}$; between 8 and 16 it is $2^{-49} = 1.8 \times 10^{-15}$. The result of every operation is **rounded** to the nearest double. A sum whose exact value is close to 8 can therefore come out only as a multiple of 2^{-50} (just below 8) or of 2^{-49} (just above 8).

The staircase, line by line. Near its root the exact sum is $S(\mu) = 8 + N'\,(\mu - \mu_{root})$. Added up directly in doubles, the computed residual $D(\mu) = S(\mu) - 8$ is exactly zero whenever the computed sum is the double 8 itself, and that happens whenever S lies within half a spacing of 8:

$$8 - 2^{-51} \le S(\mu) \le 8 + 2^{-50}.$$

Rule: rounding to the nearest double; half the spacing below 8 is $\frac{1}{2}2^{-50} = 2^{-51}$, half the spacing above is $\frac{1}{2}2^{-49} = 2^{-50}$.

$$\Delta\mu = \frac{2^{-51} + 2^{-50}}{N'} = \frac{3 \cdot 2^{-51}}{N'} = \frac{1.33 \times 10^{-15}}{1.242 \times 10^{-6}} = 1.07 \times 10^{-9}.$$

Rule: an interval of length $3 \cdot 2^{-51}$ in S is an interval of length $3 \cdot 2^{-51}/N'$ in μ, because S changes by N' per unit of μ. So in the computer the direct residual is a **staircase**: constant over intervals of about 10^{-9} in μ, jumping by one spacing between them, and exactly zero over a whole interval about 10^{-9} wide. Notebook 16c measures this interval as 1.05×10^{-9} wide, from 8.25×10^{-10} below the root to 2.30×10^{-10} above it; its position is shifted from the ideal one by the rounding of the individual terms and of the partial sums along the way (Figure 16c.2).

Why bisection then stops at the wrong place. Bisection on the residual asks at each midpoint only one question: is $D(mid) < 0$? If yes, the root is above mid; if not, at or below it. On the zero interval the answer is always "not below zero", so every midpoint inside it becomes the new upper end, and the search converges to the **left end** of the zero interval, about 8.3×10^{-10} below the true root. That is the faulty value of the first cross-check: Notebook 16c reproduces 0.2100104489071649 in all sixteen digits by bisection on the direct sum (In [7]). The record's Rust solver now writes for every thermal state the root that the former direct count would give on the same final levels, minus the present μ, in the column `mu_direct_count_minus_mu` of `Revision/kohn_sham/results/thermo/thermodynamics.csv`; for N8_lamm1_a00_T10 it is -8.267×10^{-10}.

Deciding which value is right: 40 digits and Newton's method. To decide, the checker recomputed μ from each solver's own final levels with 40 significant digits, using the package mpmath, which computes with as many digits as one asks for (slowly, in software). With 40 digits the rounding of the sum is about $10^{-40}N$, which moves the root by about $10^{-40}N/N' < 10^{-33}$: far below anything a double can hold. The root is found by **Newton's method**. Line by line: let μ_k be a guess.

$$N(\mu) \approx N(\mu_k) + N'(\mu_k)\,(\mu - \mu_k).$$

Rule: near μ_k a smooth function is close to its tangent line (Taylor's theorem to first order).

$$N(\mu_k) + N'(\mu_k)\,(\mu_{k+1} - \mu_k) = N \quad \Longrightarrow \quad \mu_{k+1} = \mu_k - \frac{N(\mu_k) - N}{N'(\mu_k)}.$$

Rule: the next guess is where the tangent line reaches the value N; subtract $N(\mu_k)$ and divide by $N'(\mu_k)$.

Why Newton's method doubles the digits, line by line. Let $e_k = \mu_k - \mu^*$ be the error of the guess, μ^* the root, and write N', N'' for the derivatives at μ^*.

$$N(\mu_k) - N = N' e_k + \tfrac{1}{2} N'' e_k^2 + \dots, \qquad N'(\mu_k) = N' + N'' e_k + \dots$$

Rule: Taylor's theorem around μ^*, with $N(\mu^*) = N$.

$$e_{k+1} = e_k - \frac{N' e_k + \frac{1}{2} N'' e_k^2}{N' + N'' e_k} = e_k - e_k\Big(1 + \tfrac{1}{2}\tfrac{N''}{N'} e_k\Big)\Big(1 - \tfrac{N''}{N'} e_k\Big) + \dots = \frac{N''}{2N'}\, e_k^2 + \dots$$

Rule: subtract μ^* from Newton's formula; take $N' e_k$ out of the numerator and N' out of the denominator; $1/(1+s) = 1 - s + \dots$; multiply out, keeping terms up to e_k^2. The new error is proportional to the square of the old one (**quadratic convergence**): once the error is small, the number of correct digits roughly doubles at every step. Notebook 16c (Out [4]) starts in the middle of the gap and shows the distances 5.5×10^{-3}, 4.9×10^{-4}, 4.0×10^{-7}, 2.1×10^{-16} and 1.5×10^{-34}.

The diagnosis. The 40-digit root on the Rust levels is 0.21001044973390364544 and on the reference levels 0.21001044973430543050; they differ by 4.0×10^{-13}, which is how much the two solvers' levels differ (each is uncertain by about 10^{-12}). The faulty Rust value was 8.3×10^{-10} below both. So the levels were right and the root-finding was wrong (the cross-check's check `thermo_mu_high_precision` now compares these roots in all 270 level sets, worst ratio 0.050: `Revision/kohn_sham/reports/ks-crosscheck.json`). The reference had had the same defect: in its first complete run its μ missed its own 40-digit root by 1.15×10^{-9} in the same state (`Revision/kohn_sham/reference/README.md`, History); it was repaired in the same way.

Why the measured uncertainty did not warn. Before the repair the canonical and the refined Rust runs computed μ with the same direct count, so both made almost the same rounding error, and their difference, from which U_{Rust} is measured (Section 16.6), did not contain it. An uncertainty measured by repeating a computation measures only the errors that the repetition changes. After the repair the refined run computes the root with a second, exactly equivalent form whose rounding takes a different path, so that their difference now contains the rounding error of the root (`Revision/kohn_sham/reports/ks-rust-determinism.json`, check `refined_mermin_root_path`). This is the deeper lesson of the episode, and the reason why a truly independent program is worth the effort.

The repair: a well-conditioned form, line by line. The trouble is that the direct sum adds numbers of size 1 (the full occupations) to get a total near 8 and then subtracts 8, so its rounding errors are of size $\epsilon_{mach} \cdot 8$, while the interesting part, $P - H_{th}$, is about 10^{-9} in size. The repair rewrites the residual exactly so that the large numbers are added only as whole numbers. Split the levels into those below μ ($x_i < 0$) and those above ($x_i \geq 0$).

$$f(x) + f(-x) = \frac{1}{1+e^x} + \frac{1}{1+e^{-x}} = \frac{1}{1+e^x} + \frac{e^x}{e^x+1} = 1.$$

Rule: multiply the numerator and the denominator of the second fraction by e^x; then the two fractions have the same denominator.

$$\sum_i g_i f(x_i) - N = \sum_{\text{below}} g_i (1 - f(-x_i)) + \sum_{\text{above}} g_i f(x_i) - N.$$

Rule: below μ write each occupation as $f(x_i) = 1 - f(-x_i)$.

$$W(\mu) = \Big(\sum_{\text{below}} g_i - N \Big) - \sum_{\text{below}} g_i \, f(-x_i) + \sum_{\text{above}} g_i \, f(x_i) = -d - H_{th} + P.$$

Rule: collect the terms; $d = N - \sum_{\text{below}} g_i$ is a whole number, H_{th} the thermal holes and P the thermal particles. The value of W is exactly that of the direct residual; only the rounding differs. The bracket d is a sum of whole numbers, which doubles add without any error. H_{th} and P are sums of small positive numbers, each computed with a relative error of about ϵ_{mach}, so near the root W is known to about $\epsilon_{mach}(P + H_{th})$, here a few times 10^{-24}, instead of $\epsilon_{mach} \cdot 8$. The reference solver's module uses exactly this form (`mermin_residual` in `Revision/kohn_sham/reference/ks_fd.py`); the Rust solver uses its logarithm, $\ln(P + d_-) - \ln(H_{th} + d_+)$ with $d_\pm = \max(\pm d, 0)$, which is nearly a straight line in μ (the form LogBalance of `Revision/kohn_sham/solver/src/mermin.rs`), and its refined run uses the linear form (LinearDeviation).

The rounding bounds, line by line. How large can the error of a computed root be?

$$N' \, (\mu_c - \mu^*) + \delta R = 0 \quad \Longrightarrow \quad |\mu_c - \mu^*| = \frac{|\delta R|}{N'}.$$

Rule: near the root the computed residual is the tangent line plus its rounding error δR, and the computed root μ_c is where it vanishes. A sum of n terms in doubles has a rounding error of at most about $n \, \epsilon_{mach}$ times the size of the terms. For the direct sum the terms add up to N, so $|\delta R| \lesssim n \, \epsilon_{mach} N$; for the well-conditioned form they add up to $P + H_{th} + |d|$. The Rust solver's documentation states the complete first-order bounds with generous constants (`Revision/kohn_sham/solver/src/mermin.rs`, its header; n the number of levels, g_{max} the largest degeneracy, $\langle |\varepsilon - \mu| \rangle$ the mean distance of the levels from μ weighted with $gf(1-f)$, and $\Lambda = \max(|\ln(P + d_-)|, |\ln(H_{th} + d_+)|)$):

$$B_{direct} = \epsilon_{mach} \Big[(n+2) \, \frac{N}{N'} + 3 \, \langle |\varepsilon - \mu| \rangle + T(\ln g_{max} + 3) + 2|\mu| \Big],$$

$$B_{well} = \epsilon_{mach} \Big[(n + 2 + \Lambda) \, \frac{P + H_{th} + |d|}{N'} + 3 \, \langle |\varepsilon - \mu| \rangle + T(\ln g_{max} + 3) + 2|\mu| \Big].$$

The extra terms count the rounding of the arguments x_i, of the logarithms and of the returned double. For N8_lamm1_a00_T10 ($n = 7$ Rust levels, $N' = 1.242072 \times 10^{-6}$) the first term of B_{direct} is $9 \cdot 2.22 \times 10^{-16} \cdot 8 / 1.242 \times 10^{-6} = 1.29 \times 10^{-8}$, and the record states $B_{direct} = 1.287 \times 10^{-8}$ and $B_{well} = 3.154 \times 10^{-16}$ (`Revision/kohn_sham/reports/ks-rust-mermin-roots.json`, state N8_lamm1_a00_T10). The faulty error, 8.27×10^{-10}, lies well inside B_{direct}: it is about 0.58 of the shift $\epsilon_{mach} N / N' = 1.43 \times 10^{-9}$ that a single rounding of the size $\epsilon_{mach} N$ causes. The repaired Rust value differs from the 40-digit root by 2.5×10^{-17} (same report, muRun_minus_root), inside B_{well}; over all 135 thermal states the repaired μ lies within its bound (same report, check `solver_mu_within_rounding_bound`), and in the cross-check the largest distance of a Rust μ from the 40-digit root on its own levels is 6.7×10^{-16} (`Revision/kohn_sham/reports/ks-crosscheck.json`, check `thermo_mu_rounding_diagnostic`).

Where the danger lies. The bound B_{direct} is large only where N' is tiny, that is, where a gap is many times T. Among the 45 thermal states with $N = 8$ this happens only at the first slice and the lowest temperature, where the bound reaches 10^{-8}; along the history 3-space inflates while the

extra times deflate, the 3-momenta are redshifted by $e^{-a_{4,0}}$, the levels above the gap move down, the gap closes, N' grows, and the bound falls to about 10^{-15} (Figure 16c.5). The three states with the largest direct-sum errors are the three couplings at $a_{4,0} = 0$ and $T = 0.01$: -8.27×10^{-10}, $+2.72 \times 10^{-10}$ and $+6.96 \times 10^{-11}$ (Notebook 16c, Out [11]; the same numbers are in `Revision/kohn_sham/reports/ks-rust-solver.json`, check `thermo_mu_well_conditioned_root`).

Status. PROVED: the slope formula, the uniqueness of the root, the exact rewriting $W = -d - H_{th} + P$, Newton's formula and its quadratic convergence; the rounding bounds are first-order estimates derived in the Rust documentation and confirmed against 40-digit roots for every thermal state (check `solver_mu_within_rounding_bound`). COMPUTED: every number of this section, from the records named with it and reproduced by Notebook 16c.

16.21 Example: the Mermin root (Notebook 16c)

Notebook 16c reconstructs the diagnosis and the repair from the records. For N8_lamm1_a00_T10 it reads the final levels of both solvers, computes μ with 40 digits by Newton's method, evaluates the direct residual in doubles near the root and shows the staircase, reproduces the faulty value of the first cross-check by bisection on the direct sum and the correct value by bisection on the well-conditioned form, and evaluates the rounding bounds. Then it repeats the 40-digit comparison of the cross-check for all 45 thermal states with eight quanta, for the levels of both solvers, and reproduces the recorded roots, bounds, tolerances and ratios. It needs no Rust, runs in about half a minute, draws six figures and ends with the line ALL 26 CHECKS PASSED (notebook 16c).

16.22 How to run Notebook 16c

Step 1. What this notebook does and what it needs.

Notebook 16c (How the cross-check caught a rounding error: the Mermin root) is the file `Revision/textbook/notebooks/16c_mermin_root.ipynb` of the repository Dirac_claude. The first cross-check of the two Kohn-Sham solvers failed on the chemical potential of one thermal state. This notebook reconstructs the diagnosis and the repair from the records: it computes the chemical potential of that state with 40 significant digits by Newton's method from the final levels of both solvers, shows why ordinary computer numbers locate it only to about one part in a billion when the occupations are simply added up, reproduces the faulty value of the first cross-check by bisection on that direct sum and the correct value by the well-conditioned form that both solvers use now, computes the rounding bounds that predict such errors, and repeats the 40-digit comparison of the cross-check for all 45 thermal states with eight particles, reproducing the recorded roots, bounds, tolerances and ratios. It needs a computer with Windows 11, macOS or Linux, an internet connection for the installation, the program Git, and Python 3.12 or newer (the notebooks were built with Python 3.14.5) with these packages at exactly these versions: numpy 2.4.6, sympy 1.14.0, mpmath 1.3.0, matplotlib 3.11.0, jupyterlab 4.4.10, nbformat 5.10.4, nbclient 0.10.2, ipykernel 7.1.0 and nbconvert 7.16.6. The notebook itself imports numpy, mpmath and matplotlib; the other packages run Jupyter, the program that shows and runs notebooks. It does not need Rust.

Step 2. Install Git and Python (once per computer).

A terminal is the window in which you type commands: on Windows the app Windows PowerShell (or Terminal), on macOS the app Terminal (it runs the shell zsh), on Linux any terminal (it runs

the shell bash). Type every command of this section into a terminal exactly as printed, one line at a time, and press Enter after each line.

Windows: download Git from https://git-scm.com/download/win and install it with the default choices. Download Python from https://www.python.org/downloads/ and run the installer; in its first window tick the box "Add python.exe to PATH" before you click "Install Now".

macOS: download Python from https://www.python.org/downloads/ and run the installer. Then open the app Terminal and run this command, which installs Git and the compiler tools:

macOS (zsh):

```
xcode-select --install
```

Linux (Debian or Ubuntu; other distributions have packages of the same names): run these two commands:

Linux (bash):

```
sudo apt update
sudo apt install git python3 python3-venv
```

Then close the terminal and open a NEW one (a terminal opened before the installation does not know the new programs), and check the version of Python; it must print 3.12 or a higher number:

Windows (PowerShell):

```
py -3 --version
```

macOS (zsh) and Linux (bash):

```
python3 --version
```

If an older Linux prints a lower number (Ubuntu 22.04 has Python 3.10), install Python 3.12 with the following three commands, and in Step 3 type `python3.12` instead of `python3` in the command that creates the environment:

Linux (bash), only when the version is too low:

```
sudo add-apt-repository ppa:deadsnakes/ppa
sudo apt update
sudo apt install python3.12 python3.12-venv
```

Step 3. Get the repository and install the packages (once per computer).

The commands below download the repository (a few hundred megabytes; the folder then needs up to about 1 GB of disk space) into the folder Dirac_claude inside your home folder, create a private Python environment in the folder dirac-book-env inside your home folder (a private environment is a folder with its own copy of Python and of the packages, so that nothing else on your computer is

changed), activate it (from then on the commands `python` and `jupyter` typed in this terminal are those of the environment, and the prompt starts with (dirac-book-env)), and install the packages at the pinned versions (this downloads about 90 MB and takes a few minutes; the environment takes about 400 MB of disk space). If you have done this step before, for this or for another notebook, skip it and go to Step 4; to get the newest version of the repository, run `git pull` in the repository folder after Step 4.

Windows (PowerShell):

```
cd $HOME
git clone https://github.com/once-ere/Dirac_claude.git
py -3 -m venv "$HOME\dirac-book-env"
Set-ExecutionPolicy -ExecutionPolicy RemoteSigned -Scope Process -Force
& "$HOME\dirac-book-env\Scripts\Activate.ps1"
python -m pip install --upgrade pip
python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
```

The line with `Set-ExecutionPolicy` allows PowerShell to run the activation script in this one window only; it changes nothing permanently.

macOS (zsh):

```
cd ~
git clone https://github.com/once-ere/Dirac_claude.git
python3 -m venv ~/dirac-book-env
source ~/dirac-book-env/bin/activate
python -m pip install --upgrade pip
python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
```

Linux (bash):

```
cd ~
git clone https://github.com/once-ere/Dirac_claude.git
python3 -m venv ~/dirac-book-env
source ~/dirac-book-env/bin/activate
python -m pip install --upgrade pip
python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
```

Step 4. In every new terminal: activate the environment and go into the repository folder.

Every later step starts in the repository folder with the environment active. Run these lines whenever you open a new terminal (they do no harm if the environment is already active):

Windows (PowerShell):

```
Set-ExecutionPolicy -ExecutionPolicy RemoteSigned -Scope Process -Force
& "$HOME\dirac-book-env\Scripts\Activate.ps1"
cd "$HOME\Dirac_claude"
```

macOS (zsh) and Linux (bash):

```
source ~/dirac-book-env/bin/activate
cd ~/Dirac_claude
```

Step 5. Run the notebook in JupyterLab.

In the repository folder, with the environment active, run these two lines (the first one goes into the folder of the notebooks):

Windows, macOS and Linux:

```
cd Revision/textbook/notebooks
jupyter lab 16c_mermin_root.ipynb
```

JupyterLab opens in your web browser and shows the notebook (if no browser window opens, copy the address that starts with `http://localhost:8888/lab` from the terminal into the address bar of your browser). The name at the top right of the notebook must read Python 3 (ipykernel). Choose the menu Run > Run All Cells. While a cell runs, the label to its left shows `[*]`; when it has finished, the label shows a number. The notebook has finished when the last code cell shows a number; this takes about 1 minute on a typical laptop. Scroll to the end and compare the last printed lines with the lines in the step "What the notebook writes and what you must see" below. To keep the results, save the notebook (menu File > Save Notebook). To stop JupyterLab, choose the menu File > Shut Down, or press Ctrl+C twice in the terminal.

Step 6. Or run the notebook without a browser (headless).

In the repository folder, with the environment active, run:

Windows, macOS and Linux:

```
cd Revision/textbook/notebooks
jupyter nbconvert --to notebook --execute --inplace 16c_mermin_root.ipynb
```

This runs every cell from the top to the bottom and saves the results into the notebook file. A failed check stops it with an error message that contains AssertionError and the name of the check. If the command ends with a line that starts with `[NbConvertApp] Writing` and shows no error, every check passed; open the notebook with `jupyter lab 16c_mermin_root.ipynb` (in the same folder, without running the cells again) to read the printed lines and see the figures.

Step 7. What the notebook writes and what you must see.

The notebook writes (or overwrites) these files:

- `Revision/textbook/figures/16c.captions.json`

- `Revision/textbook/figures/16c_1_levels_and_occupations.png`
- `Revision/textbook/figures/16c_2_residual_staircase.png`
- `Revision/textbook/figures/16c_3_convergence_paths.png`
- `Revision/textbook/figures/16c_4_errors_versus_bound.png`
- `Revision/textbook/figures/16c_5_conditioning_map.png`
- `Revision/textbook/figures/16c_6_crosscheck_ratios.png`

It changes no other file of the repository; running it headless or saving it in JupyterLab also rewrites the notebook file itself. It does not use the internet while it runs. The files it writes are the same files that are stored in the repository (on another computer a figure may differ in a few bytes, which is harmless). To get the stored versions back, run this command in the repository folder (it also undoes every change you made yourself in the folder Revision/textbook):

Windows, macOS and Linux:

```
git checkout -- Revision/textbook
```

Every check of the notebook prints a line that starts with PASS. At the end of the notebook (the output of its last code cell) you must see exactly these lines:

```
PASS every figure file of this notebook exists
ALL 26 CHECKS PASSED (notebook 16c)
```

and the notebook must show 6 figures below the cells that draw them.

Step 8. If something goes wrong.

- "ModuleNotFoundError: No module named ..." in the notebook: JupyterLab was started without the environment. Stop it (menu File > Shut Down), do Step 4, and start it again. If the error remains, another Python installation has registered its own kernel called python3; with the environment active, run the following command and start JupyterLab again:

```
python -m ipykernel install --user --name python3
```

- "FileNotFoundError: The repository folder was not found": the notebook was opened from a copy outside the repository. Open the file `Revision/textbook/notebooks/16c_mermin_root.ipynb` inside the folder Dirac_claude.
- "fatal: destination path 'Dirac_claude' already exists" in Step 3: the repository was downloaded before; skip the line with `git clone`.
- Windows: "running scripts is disabled on this system": run the line with `Set-ExecutionPolicy` and then the activation line again. "py is not recognized": use `python` instead of `py -3`; "python is not recognized": install Python again and tick "Add python.exe to PATH".

- Linux: "ensurepip is not available" when the environment is created: run `sudo apt install python3-venv` and repeat Step 3.
- "jupyter is not recognized" or "command not found: jupyter": the environment is not active; do Step 4. If the environment is active and the message stays, the programs jupyter-lab and jupyter-nbconvert are not in the folders where the terminal looks for programs (`python -m jupyter` does not help then: it has to find the same programs). Start them through Python itself, in the folder of the notebook: the first command below does what `jupyter lab` does, the second what the headless command does:

```
python -m jupyterlab 16c_mermin_root.ipynb
python -m nbconvert --execute --inplace 16c_mermin_root.ipynb
```

- Windows: the headless run prints a RuntimeWarning that mentions the "Proactor event loop" and zmq: this is a message of the package pyzmq, not an error; the run continues normally.
- A red box with "Matplotlib is building the font cache; this may take a moment." in the first run after the installation: this is a message, not an error; the run continues and the message does not come again.
- An AssertionError names a check that failed: choose the menu Kernel > Restart Kernel and Run All Cells; if it fails again, install the packages again with the pip commands of Step 3, because a different package version can change the last digits of a result.
- The cell that computes the 40-digit roots of the 45 states runs for half a minute or longer: this is normal. Numbers with 40 digits are computed by Python itself, not by the processor, so each operation is about a thousand times slower; the cell does about a hundred thousand of them. Wait until the label shows a number.
- An AssertionError names a comparison with a record: the reference results, the Rust results or a report were changed. Get the stored versions back and run the notebook again.

```
git checkout -- Revision/kohn_sham
```

16.23 Notebook 16c: complete text

This section prints the complete text of the notebook file `Revision/textbook/notebooks/16c_mermin_root.ipynb`: every cell in order, with the output that the stored, executed notebook holds. A text cell (Jupyter calls it a markdown cell) is printed in a frame after the label Text cell. A code cell is printed after the label In [k], where k is the number that Jupyter gives the cell when it runs it; the text that the cell prints follows after the label Out [k], and every figure that the cell draws follows as a figure with its caption.

Text cell:

```
## 1. What this notebook computes

A thermal Kohn-Sham state (temperature $T > 0$) fills its levels with the
Fermi-Dirac occupations, and one number, the **chemical potential** $\mu$, is fixed
```

by the condition that the occupations add up to the particle number N. The first cross-check of the two Kohn-Sham solvers (the Rust solver and the independent Python reference solver) FAILED on exactly this number: in the state N8_lamm1_a00_T10 the two values of μ differed by 8.27×10^{-10} (in units of the mass m), about 100 times the tolerance that had been fixed before the comparison. This notebook reconstructs the diagnosis and the repair from the records:

- it reads the final levels of that state from both solvers and computes μ again with **40 significant digits** (Newton's method, with the package mpmath); this decides which value was right;
- it shows why the ordinary numbers of a computer (about 16 digits) cannot locate μ better than about 10^{-9} when the occupations are simply added up: the computed sum is a **staircase** with steps of about 10^{-15};
- it reproduces the faulty value of the first cross-check, in all the digits the record prints, by bisection on that direct sum, and the correct value by the **well-conditioned** form of the condition that both solvers use now;
- it computes the **rounding bounds** that predict the size of such errors and reproduces those of the Rust solver's 40-digit report;
- for all 45 thermal states with $N = 8$ it repeats the cross-check's 40-digit comparison for both solvers, reproduces its table rows, and shows where the direct sum fails;
- it draws six figures.

It needs no Rust and runs in about half a minute.

Text cell:

2. How to run this notebook

Step 1. What this notebook does and what it needs.

Notebook 16c (How the cross-check caught a rounding error: the Mermin root) is the file ‘Revision/textbook/notebooks/16c_mermin_root.ipynb‘ of the repository Dirac_claude. The first cross-check of the two Kohn-Sham solvers failed on the chemical potential of one thermal state. This notebook reconstructs the diagnosis and the repair from the records: it computes the chemical potential of that state with 40 significant digits by Newton's method from the final levels of both solvers, shows why ordinary computer numbers locate it only to about one part in a billion when the occupations are simply added up, reproduces the faulty value of the first cross-check by bisection on that direct sum and the correct value by the well-conditioned form that both solvers use now, computes the rounding bounds that predict such errors, and repeats the 40-digit comparison of the cross-check for all 45 thermal states with eight particles, reproducing the recorded roots, bounds, tolerances and ratios. It needs a computer with Windows 11, macOS or Linux, an internet connection for the installation, the program Git, and Python 3.12 or newer (the notebooks were built with Python 3.14.5) with these packages at exactly these versions: numpy 2.4.6, sympy 1.14.0, mpmath 1.3.0, matplotlib 3.11.0, jupyterlab 4.4.10, nbformat 5.10.4, nbclient 0.10.2, ipykernel 7.1.0 and nbconvert 7.16.6. The notebook itself imports numpy, mpmath and matplotlib; the other packages run Jupyter, the program that shows and runs notebooks. It does not need Rust.

Step 2. Install Git and Python (once per computer).

A terminal is the window in which you type commands: on Windows the app Windows

PowerShell (or Terminal), on macOS the app Terminal (it runs the shell zsh), on Linux any terminal (it runs the shell bash). Type every command of this section into a terminal exactly as printed, one line at a time, and press Enter after each line.

Windows: download Git from https://git-scm.com/download/win and install it with the default choices. Download Python from https://www.python.org/downloads/ and run the installer; in its first window tick the box "Add python.exe to PATH" before you click "Install Now".

macOS: download Python from https://www.python.org/downloads/ and run the installer. Then open the app Terminal and run this command, which installs Git and the compiler tools:

macOS (zsh):

```
xcode-select --install
```

Linux (Debian or Ubuntu; other distributions have packages of the same names): run these two commands:

Linux (bash):

```
sudo apt update
sudo apt install git python3 python3-venv
```

Then close the terminal and open a NEW one (a terminal opened before the installation does not know the new programs), and check the version of Python; it must print 3.12 or a higher number:

Windows (PowerShell):

```
py -3 --version
```

macOS (zsh) and Linux (bash):

```
python3 --version
```

If an older Linux prints a lower number (Ubuntu 22.04 has Python 3.10), install Python 3.12 with the following three commands, and in Step 3 type ‘python3.12‘ instead of ‘python3‘ in the command that creates the environment:

Linux (bash), only when the version is too low:

```
sudo add-apt-repository ppa:deadsnakes/ppa
sudo apt update
sudo apt install python3.12 python3.12-venv
```

Step 3. Get the repository and install the packages (once per computer).

The commands below download the repository (a few hundred megabytes; the folder then needs up to about 1 GB of disk space) into the folder Dirac_claude inside your home folder, create a private Python environment in the folder dirac-book-env inside your home folder (a private environment is a folder with its own copy of Python and of the packages, so that nothing else on your computer is changed), activate it (from then on the commands ‘python‘ and ‘jupyter‘ typed in this terminal are those of the environment,

and the prompt starts with (dirac-book-env)), and install the packages at the pinned versions (this downloads about 90 MB and takes a few minutes; the environment takes about 400 MB of disk space). If you have done this step before, for this or for another notebook, skip it and go to Step 4; to get the newest version of the repository, run ‘git pull‘ in the repository folder after Step 4.

Windows (PowerShell):

```
cd $HOME
git clone https://github.com/once-ere/Dirac_claude.git
py -3 -m venv "$HOME\dirac-book-env"
Set-ExecutionPolicy -ExecutionPolicy RemoteSigned -Scope Process -Force
& "$HOME\dirac-book-env\Scripts\Activate.ps1"
python -m pip install --upgrade pip
python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
```

The line with ‘Set-ExecutionPolicy‘ allows PowerShell to run the activation script in this one window only; it changes nothing permanently.

macOS (zsh):

```
cd ~
git clone https://github.com/once-ere/Dirac_claude.git
python3 -m venv ~/dirac-book-env
source ~/dirac-book-env/bin/activate
python -m pip install --upgrade pip
python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
```

Linux (bash):

```
cd ~
git clone https://github.com/once-ere/Dirac_claude.git
python3 -m venv ~/dirac-book-env
source ~/dirac-book-env/bin/activate
python -m pip install --upgrade pip
python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
```

Step 4. In every new terminal: activate the environment and go into the repository folder.

Every later step starts in the repository folder with the environment active. Run these lines whenever you open a new terminal (they do no harm if the environment is already active):

Windows (PowerShell):

```
Set-ExecutionPolicy -ExecutionPolicy RemoteSigned -Scope Process -Force
& "$HOME\dirac-book-env\Scripts\Activate.ps1"
```

```
    cd "$HOME\Dirac_claude"
```

macOS (zsh) and Linux (bash):

```
    source ~/dirac-book-env/bin/activate
    cd ~/Dirac_claude
```

Step 5. Run the notebook in JupyterLab.

In the repository folder, with the environment active, run these two lines (the first one goes into the folder of the notebooks):

Windows, macOS and Linux:

```
    cd Revision/textbook/notebooks
    jupyter lab 16c_mermin_root.ipynb
```

JupyterLab opens in your web browser and shows the notebook (if no browser window opens, copy the address that starts with ‘http://localhost:8888/lab‘ from the terminal into the address bar of your browser). The name at the top right of the notebook must read Python 3 (ipykernel). Choose the menu Run > Run All Cells. While a cell runs, the label to its left shows ‘[*]‘; when it has finished, the label shows a number. The notebook has finished when the last code cell shows a number; this takes about 1 minute on a typical laptop. Scroll to the end and compare the last printed lines with the lines in the step "What the notebook writes and what you must see" below. To keep the results, save the notebook (menu File > Save Notebook). To stop JupyterLab, choose the menu File > Shut Down, or press Ctrl+C twice in the terminal.

Step 6. Or run the notebook without a browser (headless).

In the repository folder, with the environment active, run:

Windows, macOS and Linux:

```
    cd Revision/textbook/notebooks
    jupyter nbconvert --to notebook --execute --inplace 16c_mermin_root.ipynb
```

This runs every cell from the top to the bottom and saves the results into the notebook file. A failed check stops it with an error message that contains AssertionError and the name of the check. If the command ends with a line that starts with ‘[NbConvertApp] Writing‘ and shows no error, every check passed; open the notebook with ‘jupyter lab 16c_mermin_root.ipynb‘ (in the same folder, without running the cells again) to read the printed lines and see the figures.

Step 7. What the notebook writes and what you must see.

The notebook writes (or overwrites) these files:

- ‘Revision/textbook/figures/16c.captions.json‘
- ‘Revision/textbook/figures/16c_1_levels_and_occupations.png‘
- ‘Revision/textbook/figures/16c_2_residual_staircase.png‘
- ‘Revision/textbook/figures/16c_3_convergence_paths.png‘
- ‘Revision/textbook/figures/16c_4_errors_versus_bound.png‘
- ‘Revision/textbook/figures/16c_5_conditioning_map.png‘

- ‘Revision/textbook/figures/16c_6_crosscheck_ratios.png‘

It changes no other file of the repository; running it headless or saving it in JupyterLab also rewrites the notebook file itself. It does not use the internet while it runs. The files it writes are the same files that are stored in the repository (on another computer a figure may differ in a few bytes, which is harmless). To get the stored versions back, run this command in the repository folder (it also undoes every change you made yourself in the folder Revision/textbook):

Windows, macOS and Linux:

```
git checkout -- Revision/textbook
```

Every check of the notebook prints a line that starts with PASS. At the end of the notebook (the output of its last code cell) you must see exactly these lines:

```
PASS every figure file of this notebook exists
ALL 26 CHECKS PASSED (notebook 16c)
```

and the notebook must show 6 figures below the cells that draw them.

Step 8. If something goes wrong.

- "ModuleNotFoundError: No module named ..." in the notebook: JupyterLab was started without the environment. Stop it (menu File > Shut Down), do Step 4, and start it again. If the error remains, another Python installation has registered its own kernel called python3; with the environment active, run the following command and start JupyterLab again:

  ```
  python -m ipykernel install --user --name python3
  ```

- "FileNotFoundError: The repository folder was not found": the notebook was opened from a copy outside the repository. Open the file ‘Revision/textbook/notebooks/16c_mermin_root.ipynb‘ inside the folder Dirac_claude.
- "fatal: destination path ’Dirac_claude’ already exists" in Step 3: the repository was downloaded before; skip the line with ‘git clone‘.
- Windows: "running scripts is disabled on this system": run the line with ‘Set-ExecutionPolicy‘ and then the activation line again. "py is not recognized": use ‘python‘ instead of ‘py -3‘; "python is not recognized": install Python again and tick "Add python.exe to PATH".
- Linux: "ensurepip is not available" when the environment is created: run ‘sudo apt install python3-venv‘ and repeat Step 3.
- "jupyter is not recognized" or "command not found: jupyter": the environment is not active; do Step 4. If the environment is active and the message stays, the programs jupyter-lab and jupyter-nbconvert are not in the folders where the terminal looks for programs (‘python -m jupyter‘ does not help then: it has to find the same programs). Start them through Python itself, in the folder of the notebook: the first command below does what ‘jupyter lab‘ does, the second what the headless command does:

  ```
  python -m jupyterlab 16c_mermin_root.ipynb
  python -m nbconvert --execute --inplace 16c_mermin_root.ipynb
  ```

- Windows: the headless run prints a RuntimeWarning that mentions the "Proactor event loop" and zmq: this is a message of the package pyzmq, not an error; the run continues

  normally.
- A red box with "Matplotlib is building the font cache; this may take a moment." in the first run after the installation: this is a message, not an error; the run continues and the message does not come again.
- An AssertionError names a check that failed: choose the menu Kernel > Restart Kernel and Run All Cells; if it fails again, install the packages again with the pip commands of Step 3, because a different package version can change the last digits of a result.
- The cell that computes the 40-digit roots of the 45 states runs for half a minute or longer: this is normal. Numbers with 40 digits are computed by Python itself, not by the processor, so each operation is about a thousand times slower; the cell does about a hundred thousand of them. Wait until the label shows a number.
- An AssertionError names a comparison with a record: the reference results, the Rust results or a report were changed. Get the stored versions back and run the notebook again.

```
    git checkout -- Revision/kohn_sham
```

The first code cell below (the set-up cell) repeats these instructions as comments; then it imports the packages, finds the repository folder and defines the helpers ‘save_figure‘ (saves a figure and shows it), ‘check‘ (stops with an AssertionError when a check fails, prints a PASS line when it passes), ‘report‘ (prints a key number as a RESULT line) and ‘all_checks_passed‘ (prints the last line).

In [1]:

```
# HOW TO RUN NOTEBOOK 16c (the complete instructions)
#
# STEP 1. WHAT THIS NOTEBOOK DOES AND WHAT IT NEEDS.
#
# Notebook 16c (How the cross-check caught a rounding error: the Mermin root) is the file
# Revision/textbook/notebooks/16c_mermin_root.ipynb of the repository Dirac_claude. The
# first cross-check of the two Kohn-Sham solvers failed on the chemical potential of one
# thermal state. This notebook reconstructs the diagnosis and the repair from the
# records: it computes the chemical potential of that state with 40 significant digits by
# Newton’s method from the final levels of both solvers, shows why ordinary computer
# numbers locate it only to about one part in a billion when the occupations are simply
# added up, reproduces the faulty value of the first cross-check by bisection on that
# direct sum and the correct value by the well-conditioned form that both solvers use
# now, computes the rounding bounds that predict such errors, and repeats the 40-digit
# comparison of the cross-check for all 45 thermal states with eight particles,
# reproducing the recorded roots, bounds, tolerances and ratios. It needs a computer with
# Windows 11, macOS or Linux, an internet connection for the installation, the program
# Git, and Python 3.12 or newer (the notebooks were built with Python 3.14.5) with these
# packages at exactly these versions: numpy 2.4.6, sympy 1.14.0, mpmath 1.3.0, matplotlib
# 3.11.0, jupyterlab 4.4.10, nbformat 5.10.4, nbclient 0.10.2, ipykernel 7.1.0 and
# nbconvert 7.16.6. The notebook itself imports numpy, mpmath and matplotlib; the other
# packages run Jupyter, the program that shows and runs notebooks. It does not need Rust.
#
# STEP 2. INSTALL GIT AND PYTHON (ONCE PER COMPUTER).
#
# A terminal is the window in which you type commands: on Windows the app Windows
# PowerShell (or Terminal), on macOS the app Terminal (it runs the shell zsh), on Linux
# any terminal (it runs the shell bash). Type every command of this section into a
```

```
# terminal exactly as printed, one line at a time, and press Enter after each line.
#
# Windows: download Git from https://git-scm.com/download/win and install it with the
# default choices. Download Python from https://www.python.org/downloads/ and run the
# installer; in its first window tick the box "Add python.exe to PATH" before you click
# "Install Now".
#
# macOS: download Python from https://www.python.org/downloads/ and run the installer.
# Then open the app Terminal and run this command, which installs Git and the compiler
# tools:
#
# macOS (zsh):
#     xcode-select --install
#
# Linux (Debian or Ubuntu; other distributions have packages of the same names): run
# these two commands:
#
# Linux (bash):
#     sudo apt update
#     sudo apt install git python3 python3-venv
#
# Then close the terminal and open a NEW one (a terminal opened before the installation
# does not know the new programs), and check the version of Python; it must print 3.12 or
# a higher number:
#
# Windows (PowerShell):
#     py -3 --version
#
# macOS (zsh) and Linux (bash):
#     python3 --version
#
# If an older Linux prints a lower number (Ubuntu 22.04 has Python 3.10), install Python
# 3.12 with the following three commands, and in Step 3 type python3.12 instead of
# python3 in the command that creates the environment:
#
# Linux (bash), only when the version is too low:
#     sudo add-apt-repository ppa:deadsnakes/ppa
#     sudo apt update
#     sudo apt install python3.12 python3.12-venv
#
# STEP 3. GET THE REPOSITORY AND INSTALL THE PACKAGES (ONCE PER COMPUTER).
#
# The commands below download the repository (a few hundred megabytes; the folder then
# needs up to about 1 GB of disk space) into the folder Dirac_claude inside your home
# folder, create a private Python environment in the folder dirac-book-env inside your
# home folder (a private environment is a folder with its own copy of Python and of the
# packages, so that nothing else on your computer is changed), activate it (from then on
# the commands python and jupyter typed in this terminal are those of the environment,
# and the prompt starts with (dirac-book-env)), and install the packages at the pinned
# versions (this downloads about 90 MB and takes a few minutes; the environment takes
# about 400 MB of disk space). If you have done this step before, for this or for another
# notebook, skip it and go to Step 4; to get the newest version of the repository, run
# git pull in the repository folder after Step 4.
#
```

```
# Windows (PowerShell):
#     cd $HOME
#     git clone https://github.com/once-ere/Dirac_claude.git
#     py -3 -m venv "$HOME\dirac-book-env"
#     Set-ExecutionPolicy -ExecutionPolicy RemoteSigned -Scope Process -Force
#     & "$HOME\dirac-book-env\Scripts\Activate.ps1"
#     python -m pip install --upgrade pip
#     python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
#     python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
#     python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
#
# The line with Set-ExecutionPolicy allows PowerShell to run the activation script in
# this one window only; it changes nothing permanently.
#
# macOS (zsh):
#     cd ~
#     git clone https://github.com/once-ere/Dirac_claude.git
#     python3 -m venv ~/dirac-book-env
#     source ~/dirac-book-env/bin/activate
#     python -m pip install --upgrade pip
#     python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
#     python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
#     python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
#
# Linux (bash):
#     cd ~
#     git clone https://github.com/once-ere/Dirac_claude.git
#     python3 -m venv ~/dirac-book-env
#     source ~/dirac-book-env/bin/activate
#     python -m pip install --upgrade pip
#     python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
#     python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
#     python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
#
# STEP 4. IN EVERY NEW TERMINAL: ACTIVATE THE ENVIRONMENT AND GO INTO THE REPOSITORY
# FOLDER.
#
# Every later step starts in the repository folder with the environment active. Run these
# lines whenever you open a new terminal (they do no harm if the environment is already
# active):
#
# Windows (PowerShell):
#     Set-ExecutionPolicy -ExecutionPolicy RemoteSigned -Scope Process -Force
#     & "$HOME\dirac-book-env\Scripts\Activate.ps1"
#     cd "$HOME\Dirac_claude"
#
# macOS (zsh) and Linux (bash):
#     source ~/dirac-book-env/bin/activate
#     cd ~/Dirac_claude
#
# STEP 5. RUN THE NOTEBOOK IN JUPYTERLAB.
#
# In the repository folder, with the environment active, run these two lines (the first
# one goes into the folder of the notebooks):
```

```
#
# Windows, macOS and Linux:
#     cd Revision/textbook/notebooks
#     jupyter lab 16c_mermin_root.ipynb
#
# JupyterLab opens in your web browser and shows the notebook (if no browser window
# opens, copy the address that starts with http://localhost:8888/lab from the terminal
# into the address bar of your browser). The name at the top right of the notebook must
# read Python 3 (ipykernel). Choose the menu Run > Run All Cells. While a cell runs, the
# label to its left shows [*]; when it has finished, the label shows a number. The
# notebook has finished when the last code cell shows a number; this takes about 1 minute
# on a typical laptop. Scroll to the end and compare the last printed lines with the
# lines in the step "What the notebook writes and what you must see" below. To keep the
# results, save the notebook (menu File > Save Notebook). To stop JupyterLab, choose the
# menu File > Shut Down, or press Ctrl+C twice in the terminal.
#
# STEP 6. OR RUN THE NOTEBOOK WITHOUT A BROWSER (HEADLESS).
#
# In the repository folder, with the environment active, run:
#
# Windows, macOS and Linux:
#     cd Revision/textbook/notebooks
#     jupyter nbconvert --to notebook --execute --inplace 16c_mermin_root.ipynb
#
# This runs every cell from the top to the bottom and saves the results into the notebook
# file. A failed check stops it with an error message that contains AssertionError and
# the name of the check. If the command ends with a line that starts with [NbConvertApp]
# Writing and shows no error, every check passed; open the notebook with jupyter lab
# 16c_mermin_root.ipynb (in the same folder, without running the cells again) to read the
# printed lines and see the figures.
#
# STEP 7. WHAT THE NOTEBOOK WRITES AND WHAT YOU MUST SEE.
#
# The notebook writes (or overwrites) these files:
#
# - Revision/textbook/figures/16c.captions.json
# - Revision/textbook/figures/16c_1_levels_and_occupations.png
# - Revision/textbook/figures/16c_2_residual_staircase.png
# - Revision/textbook/figures/16c_3_convergence_paths.png
# - Revision/textbook/figures/16c_4_errors_versus_bound.png
# - Revision/textbook/figures/16c_5_conditioning_map.png
# - Revision/textbook/figures/16c_6_crosscheck_ratios.png
#
# It changes no other file of the repository; running it headless or saving it in
# JupyterLab also rewrites the notebook file itself. It does not use the internet while
# it runs. The files it writes are the same files that are stored in the repository (on
# another computer a figure may differ in a few bytes, which is harmless). To get the
# stored versions back, run this command in the repository folder (it also undoes every
# change you made yourself in the folder Revision/textbook):
#
# Windows, macOS and Linux:
#     git checkout -- Revision/textbook
#
# Every check of the notebook prints a line that starts with PASS. At the end of the
```

```
# notebook (the output of its last code cell) you must see exactly these lines:
#
#     PASS every figure file of this notebook exists
#     ALL 26 CHECKS PASSED (notebook 16c)
#
# and the notebook must show 6 figures below the cells that draw them.
#
# STEP 8. IF SOMETHING GOES WRONG.
#
# - "ModuleNotFoundError: No module named ..." in the notebook: JupyterLab was started
#   without the environment. Stop it (menu File > Shut Down), do Step 4, and start it
#   again. If the error remains, another Python installation has registered its own
#   kernel called python3; with the environment active, run the following command and
#   start JupyterLab again:
#     python -m ipykernel install --user --name python3
# - "FileNotFoundError: The repository folder was not found": the notebook was opened
#   from a copy outside the repository. Open the file
#   Revision/textbook/notebooks/16c_mermin_root.ipynb inside the folder Dirac_claude.
# - "fatal: destination path 'Dirac_claude' already exists" in Step 3: the repository was
#   downloaded before; skip the line with git clone.
# - Windows: "running scripts is disabled on this system": run the line with
#   Set-ExecutionPolicy and then the activation line again. "py is not recognized": use
#   python instead of py -3; "python is not recognized": install Python again and tick
#   "Add python.exe to PATH".
# - Linux: "ensurepip is not available" when the environment is created: run sudo apt
#   install python3-venv and repeat Step 3.
# - "jupyter is not recognized" or "command not found: jupyter": the environment is not
#   active; do Step 4. If the environment is active and the message stays, the programs
#   jupyter-lab and jupyter-nbconvert are not in the folders where the terminal looks for
#   programs (python -m jupyter does not help then: it has to find the same programs).
#   Start them through Python itself, in the folder of the notebook: the first command
#   below does what jupyter lab does, the second what the headless command does:
#     python -m jupyterlab 16c_mermin_root.ipynb
#     python -m nbconvert --execute --inplace 16c_mermin_root.ipynb
# - Windows: the headless run prints a RuntimeWarning that mentions the "Proactor event
#   loop" and zmq: this is a message of the package pyzmq, not an error; the run
#   continues normally.
# - A red box with "Matplotlib is building the font cache; this may take a moment." in
#   the first run after the installation: this is a message, not an error; the run
#   continues and the message does not come again.
# - An AssertionError names a check that failed: choose the menu Kernel > Restart Kernel
#   and Run All Cells; if it fails again, install the packages again with the pip
#   commands of Step 3, because a different package version can change the last digits of
#   a result.
# - The cell that computes the 40-digit roots of the 45 states runs for half a minute or
#   longer: this is normal. Numbers with 40 digits are computed by Python itself, not by
#   the processor, so each operation is about a thousand times slower; the cell does
#   about a hundred thousand of them. Wait until the label shows a number.
# - An AssertionError names a comparison with a record: the reference results, the Rust
#   results or a report were changed. Get the stored versions back and run the notebook
#   again.
#     git checkout -- Revision/kohn_sham
#
# ------------------------------------------------------------------------------------
```

```
# ============================================================================
# THE SET-UP (the same in every notebook of this book; it computes no physics)
# ============================================================================
import json  # reads and writes JSON files (text files that hold names and numbers)
import os  # reads the environment variable TEXTBOOK_OUTPUT_ROOT (explained below)
import textwrap  # breaks long printed text into lines of at most 89 characters
from pathlib import Path  # file and folder paths that work on Windows, macOS and Linux

## 3. The words used in this notebook

- **Level** $\varepsilon_i$: an allowed one-particle energy of the Kohn-Sham problem
  (units of the mass $m$). **Degeneracy** $g_i$: the number of states with that
  energy. In this model $g = 4\,r_3(n_2)$, where $n_2 = |\vec n|^2$ labels the shell
  of the 3-space momentum and $r_3(n_2)$ counts the whole-number points
  $(a, b, c)$ with $a^2 + b^2 + c^2 = n_2$ (the factor 4 counts four blocks of the
  spinor equation).
- **Fermi-Dirac occupation** $f(x) = 1/(1 + e^x)$ with $x = (\varepsilon - \mu)/T$:
  the average number of particles in one state; it lies between 0 and 1.
- **Chemical potential** $\mu$: the energy at which the occupation is one half.
- **Mermin condition**: $N(\mu) = \sum_i g_i\,f(x_i) = N$, the equation that fixes
  $\mu$. Its solution is called the **root**.
- **Gap**: an energy interval without levels. When the gap is much larger than $T$
  the state is in the **activated regime**: very few particles are thermally lifted
  across it.
- **Thermal holes** $H_{th} = \sum_{\varepsilon_i < \mu} g_i\,(1 - f(x_i))$ (missing
  particles below $\mu$) and **thermal particles**
  $P = \sum_{\varepsilon_i > \mu} g_i\,f(x_i)$ (particles above $\mu$).
- **Newton's method** and **bisection**: two ways to find a root, explained where
  they are used.
- **Double**: the ordinary number of a computer, with 53 binary digits (about 16
  decimal digits). **Machine epsilon** $\epsilon_{mach} = 2^{-52} \approx
  2.2\times10^{-16}$: the relative distance between neighbouring doubles near 1.
- **Rounding error**: the difference between the exact result of an operation and
  the double that the computer stores.
- **40-digit arithmetic**: numbers with 40 significant decimal digits, computed by
  the package mpmath (slow, but exact far beyond what is needed here).
- **Residual**: the left side minus the right side of an equation,
  $N(\mu) - N$; it is zero at the root.
- **Conditioning**: how strongly a small error of the residual moves the root.
  **Rounding bound**: an upper limit for the error of a computed root.
- **Tolerance** and **ratio** of the cross-check: the largest difference allowed
  between the two solvers, $3(U_{ref} + U_{Rust}) + 10^{-12}\max(1, |x|)$, and the
```

  difference divided by it; a comparison passes when the ratio is at most 1.
- **State id** such as ‘N8_lamm1_a00_T10‘: $N = 8$ particles, coupling
  $-\lambda_1$ (‘lam0‘: $\lambda = 0$; ‘lamp1‘: $+\lambda_1$; ‘lamm1‘:
  $-\lambda_1$), slice $a_{4,0} = 0$ (the digits are ten times $a_{4,0}$),
  temperature $T = 0.01$ (‘T10‘; ‘T20‘: 0.02; ‘T50‘: 0.05; units of m).

Text cell:

```
## 4. The physical and mathematical situation

**The states.** The Kohn-Sham states of the fermion field dirac16complex are computed
at five instants (slices $a_{4,0} = 0, 0.5, 1, 1.5, 2$) of the PRESCRIBED BACKGROUND
history $a_4 = A H x_4$ of the author's metric: 3-space $x_1, x_2, x_3$ inflates with
the scale factor $e^{a_4}\sin^{1/6} z$, while the three extra times $x_5, x_6, x_7$
DEFLATE exponentially with $e^{-a_4}\sin^{1/6} z$; $x_4$ is the time and $x_0$ the
hidden direction. The 135 thermal states of the canonical matrix have
$N = 8, 136, 688$ particles, couplings $\lambda = 0, \pm\lambda_1$, the five slices
and $T = 0.01, 0.02, 0.05$. For each, both solvers compute the self-consistent levels
$\varepsilon_i$ and then $\mu$ from the Mermin condition
$$N(\mu) = \sum_i g_i\, f\!\left(\frac{\varepsilon_i - \mu}{T}\right) = N,
\qquad f(x) = \frac{1}{1 + e^x}.$$

**The slope of $N(\mu)$, line by line.**

- $f(x) = (1 + e^x)^{-1}$, so by the chain rule
  $f'(x) = -(1 + e^x)^{-2}\,e^x$.
- $\dfrac{e^x}{(1 + e^x)^2} = \dfrac{1}{1 + e^x}\cdot\dfrac{e^x}{1 + e^x}
  = f(x)\,(1 - f(x))$, because $1 - f(x) = \dfrac{e^x}{1 + e^x}$.
- So $f'(x) = -f(x)(1 - f(x))$.
- With $x = (\varepsilon - \mu)/T$ we have $dx/d\mu = -1/T$, and the chain rule gives
  $\dfrac{dN}{d\mu} = \sum_i g_i\, f'(x_i)\,\left(-\dfrac{1}{T}\right)
  = \dfrac{1}{T}\sum_i g_i\, f(x_i)(1 - f(x_i))$.
- Every term is positive, so $N(\mu)$ increases with $\mu$ and the root is unique.

**The activated regime.** In N8_lamm1_a00_T10 the eight particles exactly fill the
two lowest levels (each 4-fold, at $\varepsilon \approx 0.00025$); the next level
lies at $0.43$, so the gap is 43 times $T = 0.01$. Then $\mu$ sits near the middle
of the gap, where the few thermal holes below balance the few thermal particles
above, and $f(1 - f)$ is tiny for every level: $dN/d\mu \approx 10^{-6}$. A flat
$N(\mu)$ makes the root hard to locate: an error $\delta$ of the computed residual
moves the root by $\delta/(dN/d\mu)$ (the tangent line), a million times more.

**The history (records).** The cross-check compares every number of the two solvers
with the rule $|x_{Rust} - x_{ref}| \le 3(U_{ref} + U_{Rust}) +
10^{-12}\max(1,|x|)$, fixed in the program before any comparison. Its first run, on
a subset of the states, failed the check ‘thermo_state_functions‘ in
N8_lamm1_a00_T10: the Rust $\mu$ was $0.2100104489071649$, the reference $\mu$
$0.2100104497343054$, a difference of $8.27\times10^{-10}$ against a tolerance of
$7.97\times10^{-12}$. The tolerance was NOT widened. Instead the checker recomputed
$\mu$ with 40 digits from each solver's own levels: the two 40-digit roots agreed to
$4\times10^{-13}$, so the levels agreed and the Rust root was wrong. The Rust
solver computed $\mu$ by bisection on the direct sum $\sum g f - N$; it was repaired
(file ‘solver/src/mermin.rs‘). The reference solver had the same defect in its first
```

```
complete run (its $\mu$ missed its own 40-digit root by $1.15\times10^{-9}$ in the same
state); it was repaired the same way. This notebook repeats each step of that
diagnosis with numbers it computes itself.
```

Text cell:

```
## 5. The levels of the state N8_lamm1_a00_T10

The next cell reads, for the state N8_lamm1_a00_T10, the final levels of the Rust
solver (stored with its canonical numerics in the cross-check's measurement file
‘rust-refinement.json‘), the final levels of the reference solver (its result file
‘thermo/N8_lamm1_a00_T10.json‘; the degeneracy is computed from the shell $n_2$ as
$4\,r_3(n_2)$), and the committed values of $\mu$ of both solvers. It also reads the
numbers of the history from the two README files with a text pattern, so that the
notebook uses the recorded values, not copies typed by hand. It prints the levels
side by side and checks that both solvers have the same levels (within their
uncertainties) and the same filling.
```

## 6. The root with 40 digits: Newton's method

**Newton's method, line by line.** Suppose $\mu_k$ is a guess for the root.

- Near $\mu_k$ the function is close to its tangent line:
```

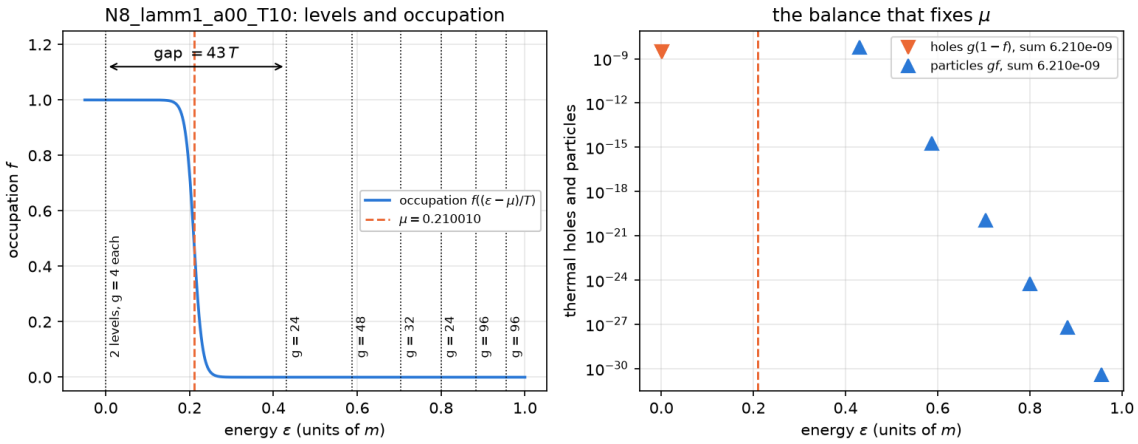

Figure 453: The thermal Kohn-Sham state N8_lamm1_a00_T10 ($N = 8$, $\lambda = -\lambda_1$, $a_{4,0} = 0$, $T = 0.01\,m$) of the reference solver. Left: the Fermi-Dirac occupation against the energy in units of m, with the levels as dotted lines and their degeneracies g; the two lowest levels hold the eight particles, the next level lies 43 times T higher, and μ (dashed) sits in the middle of this gap. Right: the thermal holes of the full levels and the thermal particles of the empty ones on a logarithmic axis; both sums are about 6×10^{-9} and cancel, which is the Mermin condition. (Notebook 16c, figure 1.)

```
  $N(\mu) \approx N(\mu_k) + N'(\mu_k)\,(\mu - \mu_k)$, where $N' = dN/d\mu$
  (section 4).
- Ask where the tangent line reaches the value $N$:
  $N(\mu_k) + N'(\mu_k)(\mu - \mu_k) = N$.
- Solve for $\mu$ (subtract $N(\mu_k)$, divide by $N'(\mu_k)$):
  $\mu_{k+1} = \mu_k - \dfrac{N(\mu_k) - N}{N'(\mu_k)}$. That is the next guess.
- Close to the root the error of the tangent line is of second order in the
  distance, so each step roughly doubles the number of correct digits
  (**quadratic convergence**).

The next cell writes Newton's method with mpmath numbers of 40 significant digits,
starts in the middle of the gap, and stops when a step is below $10^{-32}$. In 40-digit
arithmetic the rounding of the sum is about $10^{-40} N$, which moves the root by
about $10^{-40}\,N/(dN/d\mu) < 10^{-33}$: far below anything a double can hold (two
40-digit computations that add in a different order may therefore differ by about
$10^{-33}$, so the cell compares 40-digit roots to $10^{-32}$). The cell computes
the root from the Rust levels and from the reference levels and compares them with
three records: the fixture `mermin-roots-40digit.json` of the
Rust solver (made from exactly the same doubles), the checker's own 40-digit
function `mu_high_precision` (imported from `crosscheck_ks.py`), and the row
`N8_lamm1_a00_T10 mu_high_precision` of the cross-check table.
```

So the correct $\mu$ of this state is $0.21001044973390\dots$ on the Rust levels and
$0.21001044973430\dots$ on the reference levels; they differ by $4\times10^{-13}$,
which is how much the two solvers' levels differ (each is uncertain by about
$10^{-12}$). The faulty value of the first cross-check, $0.2100104489071649$, is
$8.3\times10^{-10}$ below both: the levels were right, the computation of $\mu$
from them was wrong. The next section shows why.
```

Text cell:

```
## 7. Why 16 digits are not enough: the staircase

**How a computer adds.** A double has 53 binary digits. Between 4 and 8 the doubles
are spaced $2^{2 - 52} = 2^{-50} \approx 8.9\times10^{-16}$ apart, between 8 and 16
they are $2^{-49} \approx 1.8\times10^{-15}$ apart. When the computer adds up the
occupations $\sum g f$, whose exact value is close to 8, the result is rounded to one
of these doubles. Now count how much the exact sum changes when $\mu$ moves by
$10^{-9}$: by $dN/d\mu \times 10^{-9} \approx 1.2\times10^{-6}\times10^{-9} =
1.2\times10^{-15}$, about one spacing. So in the computer the **direct residual**
$D(\mu) = \sum g f - N$ cannot follow $\mu$ smoothly: it stays constant over
intervals of about $10^{-9}$ in $\mu$ and then jumps by one spacing. It is a
**staircase**, and in particular it is exactly zero on a whole interval of $\mu$
about $10^{-9}$ wide. A root search that looks at $D$ can stop anywhere in that
interval.
```

```
The next cell evaluates, at 1201 values of $\mu$ within $3\times10^{-9}$ of the
40-digit root (on the Rust levels): the direct residual $D(\mu)$ in doubles; the
**well-conditioned residual** $W(\mu)$ of the reference module `ks_fd` (its function
`mermin_residual`, explained in section 8); and the exact residual with 40 digits.
```

## 8. Bisection on the two forms: the faulty value, and the repair

**Bisection.** If a function is increasing, negative at $lo$ and not negative at
$hi$, its root lies between them. Take the midpoint $mid$; if the function is
negative there, the root lies above it ($lo = mid$), otherwise at or below it
($hi = mid$). Every step halves the interval. In doubles one stops when $lo$ and
```

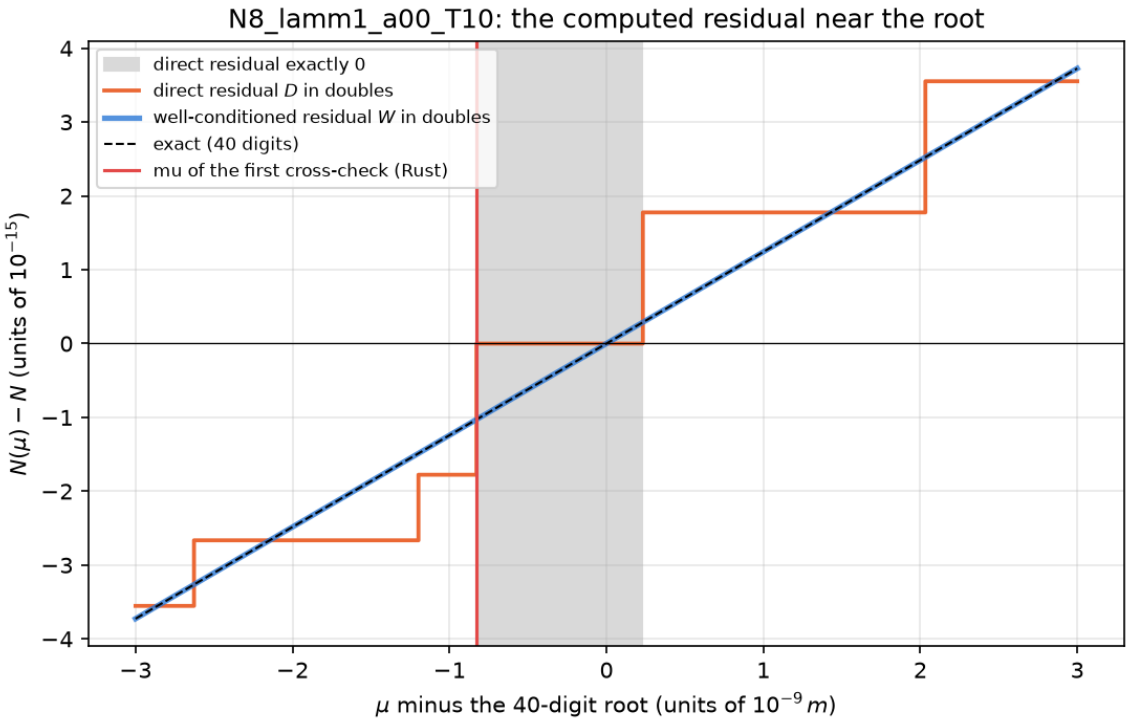

Figure 454: The residual $N(\mu) - N$ of the Mermin condition of the state N8_lamm1_a00_T10 (Rust levels) within $3 \times 10^{-9}\,m$ of the 40-digit root, horizontal axis in units of $10^{-9}\,m$, vertical axis in units of 10^{-15} particles. Added up directly in ordinary computer numbers (orange) the sum near 8 can only change in steps of 2^{-50} or 2^{-49}, so the residual is a staircase that is exactly zero on an interval about 10^{-9} wide (grey); the faulty μ of the first cross-check (red) is the left end of that interval. The well-conditioned form (blue) follows the exact line (dashed) and crosses zero at the root. (Notebook 16c, figure 2.)

```
$hi$ are neighbouring doubles (the midpoint can no longer be different from both).
This is how both solvers searched for $\mu$, starting from an interval that contains
every level.

**The well-conditioned form, line by line.** Split the sum into the levels below
$\mu$ ($x_i < 0$) and the levels above ($x_i \ge 0$).

- $f(x) + f(-x) = \dfrac{1}{1 + e^x} + \dfrac{1}{1 + e^{-x}}
  = \dfrac{1}{1 + e^x} + \dfrac{e^x}{e^x + 1} = 1$ (multiply the second fraction by
  $e^x/e^x$), so $f(x) = 1 - f(-x)$.
- Below $\mu$ write each occupation as $1 - f(-x_i)$:
  $\sum_i g_i f(x_i) - N = \sum_{below} g_i\,(1 - f(-x_i)) + \sum_{above} g_i\,f(x_i)
  - N$.
- Collect the ones:
  $W(\mu) = \Big(\sum_{below} g_i - N\Big) - \sum_{below} g_i\,f(-x_i)
  + \sum_{above} g_i\,f(x_i)$.
- The first bracket is a sum of whole numbers, which doubles add exactly. The second
  sum is $H_{th}$, the thermal holes, and the third is $P$, the thermal particles; both
  are sums of small positive numbers, each computed with a relative error of about
  $10^{-16}$. Near the root $W$ is small and is known to about $10^{-16}$ of the size
  of $H_{th}$ and $P$ (here $6\times10^{-9}$), instead of $10^{-16}$ of $N = 8$.

The value is the same as before (it is an exact rewriting); only the rounding is
different. The next cell runs bisection on both forms with the Rust levels, starting
from the interval the reference uses, and records every midpoint.
```

the direct sum on the reference levels misses their root by -8.271e-10
```

Text cell:

```
The direct sum also misses on the reference levels, by almost the same amount
(printed above): their levels agree with the Rust levels to about $10^{-12}$, so
their staircase has a zero interval at almost the same place, and bisection again
stops at its left end. (The reference's own first complete run missed by
$1.15\times10^{-9}$; it computed $\mu$ on each of its three grids and then combined
them, so that number is not the same computation and is not reproduced here.)

The next figure follows the three searches step by step: the distance of each guess
from the 40-digit root, on a logarithmic axis. Bisection halves the distance at every
```

```
step (a straight line on this axis); on the direct sum it stops improving near
$10^{-9}$, because from there on it only explores the zero interval of the
staircase; on the well-conditioned form it goes on down to the spacing of the doubles
near $\mu$, about $3\times10^{-17}$. Newton's method with 40 digits needs only a few
steps, and the number of correct digits roughly doubles at each.
```

```
## 9. The rounding bounds: predicting the error
```

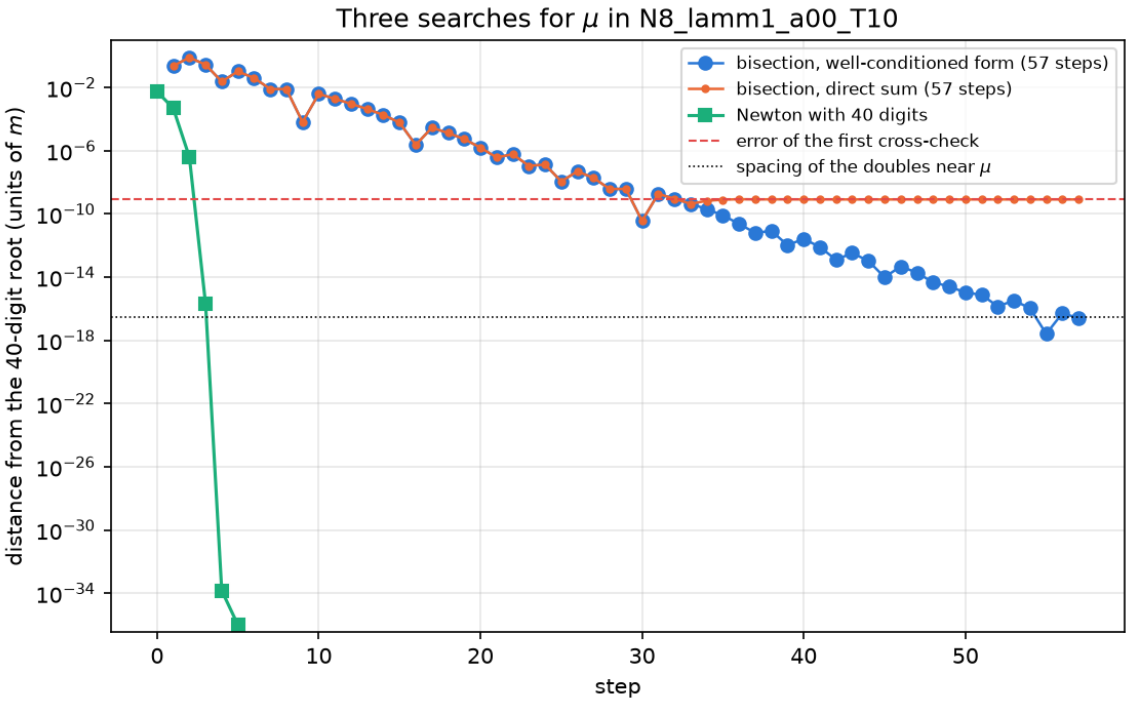

Figure 455: The distance of each guess for μ from the 40-digit root, units of m, logarithmic, against the step number, for the state N8_lamm1_a00_T10 with the Rust levels. Bisection halves the distance at every step; on the direct sum (orange) it stalls at 8.3×10^{-10}, the error of the first cross-check (red dashed), because the computed sum is zero on a whole interval; on the well-conditioned form (blue) it reaches the spacing of the doubles (dotted). Newton's method with 40 digits (green) doubles the number of correct digits at each step; zero distances are drawn at 10^{-36}. (Notebook 16c, figure 3.)

```
How large can the error of a computed root be? Line by line:

- Suppose the computed residual is off by $\delta R$ (rounding). Near the root the
  residual is the tangent line $N'(\mu - \mu_{root})$, so the computed root sits
  where $N'(\mu - \mu_{root}) + \delta R = 0$, that is $\mu - \mu_{root} =
  -\delta R/N'$.
- Adding $n$ numbers in doubles makes an error of at most about $n\,\epsilon_{mach}$
  times the size of the numbers. For the direct sum the numbers are the
  occupations, of total size $N$, so $|\delta R| \lesssim n\,\epsilon_{mach} N$ and
  $|\mu - \mu_{root}| \lesssim n\,\epsilon_{mach} N / N'$.
- For the well-conditioned form the numbers are $H_{th}$, $P$ and the whole number
  $d = N - \sum_{below} g$ (zero at the root of this state), so $N$ is replaced by
  $P + H_{th} + |d|$.

The Rust solver's documentation (file `solver/src/mermin.rs`) states the complete
bounds, with generous constants. Besides the summation they count the rounding of
the arguments $x_i = (\varepsilon_i - \mu)/T$ (the term with
$\langle|\varepsilon - \mu|\rangle$), the logarithms of the degeneracies and a few
constants (the term with $T$), the returned double (the term with $|\mu|$), and, for
the well-conditioned form, the logarithms with which the solver balances the two
sides $A = P + d_-$ and $B = H_{th} + d_+$ ($d_\pm = \max(\pm d, 0)$; at the root
$A = B$):
$$B_{direct} = \epsilon_{mach}\Big[(n + 2)\,\frac{N}{N'} + 3\,\langle|\varepsilon
- \mu|\rangle + T(\ln g_{max} + 3) + 2|\mu|\Big],$$
$$B_{well} = \epsilon_{mach}\Big[(n + 2 + \Lambda)\,\frac{P + H_{th} + |d|}{N'}
+ 3\,\langle|\varepsilon - \mu|\rangle + T(\ln g_{max} + 3) + 2|\mu|\Big],$$
where $n$ is the number of levels, $g_{max}$ the largest degeneracy,
$\Lambda = \max(|\ln A|, |\ln B|)$, and $\langle\cdot\rangle$ the average weighted with
$g f(1 - f)$. The next cell evaluates both at the root and compares them with the
entry of this state in the Rust solver's 40-digit report `ks-rust-mermin-roots.json`
(which prints 4 digits).

So the error of the first cross-check was no accident: it has exactly the size that
the rounding of the direct sum allows. $8.27\times10^{-10}$ is about 0.6 of the shift
that a single rounding of size $\epsilon_{mach} N$ causes, and far inside
$B_{direct} \approx 1.3\times10^{-8}$. The well-conditioned form shrinks the bound
to about $3\times10^{-16}$ (printed above), a factor of about $4\times10^{7}$.
```

Text cell:

```
## 10. All 45 thermal states with eight particles

Is N8_lamm1_a00_T10 special? The next cell repeats everything for the 45 thermal
states with $N = 8$ (3 couplings, 5 slices, 3 temperatures), for the levels of both
solvers: the 40-digit root (90 roots; this takes about half a minute), $dN/d\mu$ and
```

```
the two bounds, the bisection on the direct sum and on the well-conditioned form,
and the cross-check's comparisons. It reproduces four records:

- the 40-digit roots, $dN/d\mu$ and the two bounds of `ks-rust-mermin-roots.json`
  (the level files keep 16 digits, so the roots agree to about $10^{-17}$, not
  $10^{-35}$);
- the rows `<state> mu_high_precision` of the cross-check table: both 40-digit roots,
  the tolerance with $U_{ref}$ = the largest level uncertainty of the reference and
  $U_{Rust} = \tfrac{16}{15}\times$ the largest canonical-minus-refined level
  difference, and the ratio;
- the rows `<state> mu` (check `thermo_state_functions`): the two committed values of
  $\mu$ with $U_{ref}$ of the reference's $\mu$ and $U_{Rust} = \tfrac{16}{15}|\mu_
  {canonical} - \mu_{refined}|$;
- the check `thermo_mu_rounding_diagnostic`: each committed $\mu$ lies within
  $n\,\epsilon_{mach} N/N'$ of the root on its own levels (plus $3U$ for the
  reference, whose $\mu$ is a combination of three grids).
```

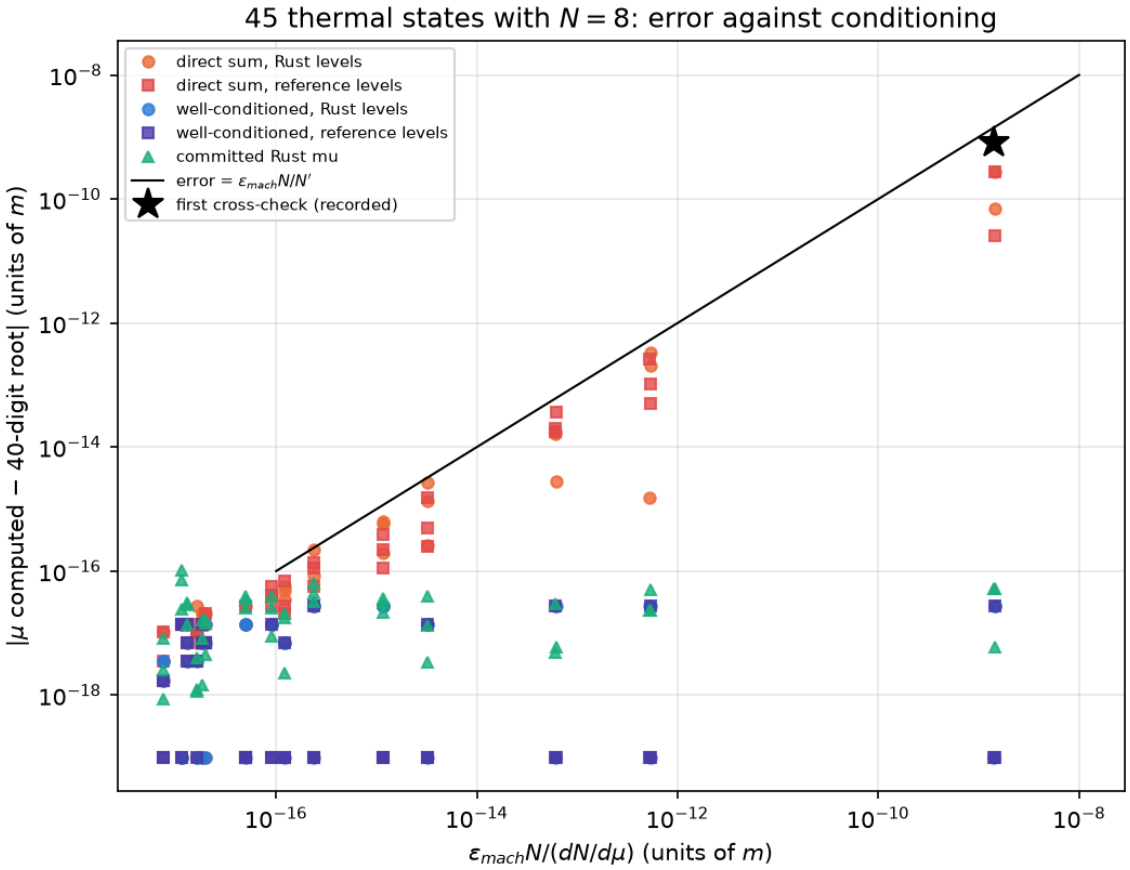

Figure 456: Errors of the computed chemical potential, in units of m, against the conditioning scale $\epsilon_{mach} N/(dN/d\mu)$ for the 45 thermal states with $N = 8$, both axes logarithmic. Bisection on the direct sum (orange: Rust levels, red: reference levels) has errors that grow with the conditioning scale and approach the line of slope 1 in the worst states; the star is the recorded error of the first cross-check. The well-conditioned form (blue, purple) and the committed repaired Rust values (green) stay near 10^{-17} for every state; exact zeros are drawn at 10^{-19}. (Notebook 16c, figure 4.)

Text cell:

```
Where in the canonical matrix is the direct sum dangerous? The next figure shows
$B_{direct}$ of the 45 states as three maps (one per coupling), with the slice
$a_{4,0}$ downwards and the temperature across; the colour and the number in each
square give $\log_{10} B_{direct}$. At $a_{4,0} = 0$ and $T = 0.01$ the gap is 43
times $T$ and the bound is $10^{-8}$. Along the history 3-space inflates and the
extra times deflate: the 3-momenta are redshifted by $e^{-a_{4,0}}$, the levels above
the gap move down, the gap shrinks, $dN/d\mu$ grows, and the bound falls towards
$10^{-15}$.
```

## 11. What the tolerance rule did

The last figure is the cross-check's view. For each of the 45 states it shows the
ratio of the $\mu$ comparison (‘thermo_state_functions‘, circles) and of the
40-digit comparison (‘thermo_mu_high_precision‘, squares), both computed above, and
the ratio of the failed first comparison, $8.27\times10^{-10}/7.97\times10^{-12}$
(red star). The rule was fixed before the comparison and was not changed afterwards:
the failure was explained (the 40-digit roots), the program was repaired, and the
same rule then passed.
```

In [14]:

```
order = sorted(range(len(ROWS)), key=lambda i: -ROWS[i]["b_r"]["direct"])

```
## 13. What this notebook showed

- The chemical potential of a thermal state is the root of
  $\sum g f((\varepsilon - \mu)/T) = N$; its slope $dN/d\mu = \sum g f(1 - f)/T$ is
  tiny when the gap is many times $T$ (activated regime), so a small error of the
  residual moves the root a lot.
- With 40 digits (Newton's method) the root of N8_lamm1_a00_T10 is
  $0.21001044973390\dots$ on the Rust levels and differs by $4\times10^{-13}$ on the
  reference levels; this reproduces the cross-check table, the checker's own
  function and the Rust fixture.
```

```
- Added up directly in doubles, the residual is a staircase in steps of $2^{-50}$
  that is exactly zero on an interval about $10^{-9}$ wide; bisection on it returns
  the recorded faulty value $0.2100104489071649$ of the first cross-check in all the
  digits the record prints.
- The exact rewriting $W = (\sum_{below} g - N) - H_{th} + P$ is computed with relative
  precision; bisection on it gives the root to $10^{-16}$, the committed repaired
  values of both solvers.
- The rounding bounds of the Rust documentation predict both errors
  ($B_{direct} \approx 1.3\times10^{-8}$, $B_{well} \approx 3\times10^{-16}$ for
  this state); our evaluation of them reproduces the Rust 40-digit report for all
  45 states with $N = 8$; the direct sum is dangerous only early in the history and
  at low $T$.
- The cross-check's tolerance, fixed in advance, caught the error (ratio about
  100); after the repair every ratio of the chemical potential in these 45 states is
  below 0.1, with the same rule.
- What this does NOT show: the 40-digit roots test the computation of $\mu$ from
  given levels. The levels themselves, the functional, the ASSUMED $Z_2$ brane, the
  filling CONVENTION and the PRESCRIBED BACKGROUND history are inputs that both
  solvers share; this notebook does not test them.
```

16.24 Line-by-line walk-through of Notebook 16c

The notebook has 15 code cells, In [1] to In [15]; the numbers they print are in Section 16.23.

In [1], the set-up cell. As in Notebook 16b, it is the set-up cell of Notebook 16a (Section 16.12) without the Rust helper; its comment lines repeat the run instructions of Section 16.22, and its name line is

```
NOTEBOOK_ID = "16c"  # this notebook: chapter 16, example c
```

In [2], the levels of N8_lamm1_a00_T10 and the history.

```
import csv  # reads tables stored as CSV files (comma-separated values)
import math  # functions of single numbers (isqrt, log10, ...)
import re  # finds patterns in text (used to read numbers out of sentences)
import sys  # the list of folders in which Python looks for modules
from functools import lru_cache  # remembers the results of a function

import mpmath as mp  # numbers with as many digits as we ask for
import numpy as np  # arrays of numbers

KS = "Revision/kohn_sham"  # the folder of the Kohn-Sham record (repository path)
STATE = "N8_lamm1_a00_T10"  # the state in which the first cross-check failed
EPS_MACH = 2.0 ** -52  # machine epsilon: neighbouring doubles near 1 differ by this
PALETTE = ["#2a78d6", "#eb6834", "#1baf7a", "#eda100", "#e87ba4", "#008300",
           "#4a3aa7", "#e34948"]  # the colours of the figures, in a fixed order
```

Besides the modules of Notebook 16a, `math` gives functions of single numbers (here `isqrt`, the whole-number square root, `log`, `log10` and `ulp`), and `lru_cache` from the module `functools` makes a function remember its results. `mpmath`, called `mp`, computes with as many digits as one asks for.

STATE is the state of the failed comparison, and EPS_MACH is the machine epsilon 2^{-52} (** is the power).

```
def read_json(relative):
    """Read a JSON file of the repository (a Revision record)."""
    return json.loads(repository_file(relative).read_text(encoding="utf-8"))

def read_csv(relative):
    """Read a CSV file of the repository: a list of rows, each row a dictionary from
    the column names to the texts in that row."""
    with open(repository_file(relative), newline="", encoding="utf-8") as handle:
        return list(csv.DictReader(handle))
```

The two reading functions of Notebook 16a (Section 16.12, In [2]).

```
@lru_cache(maxsize=None)
def r3(n2):
    """The number of whole-number points (a, b, c) with a^2 + b^2 + c^2 = n2."""
    R = math.isqrt(n2) + 1  # no coordinate can be larger than this
    return sum(1 for a in range(-R, R + 1) for b in range(-R, R + 1)
               for c in range(-R, R + 1) if a * a + b * b + c * c == n2)
```

r3(n2) counts the points (a, b, c) with whole-number coordinates and $a^2 + b^2 + c^2 = n_2$, the number $r_3(n_2)$ of Chapter 15. No coordinate can be larger than $\sqrt{n_2}$, so the three nested ranges from $-R$ to R with $R = \lfloor\sqrt{n_2}\rfloor + 1$ cover all candidates, and sum(1 for ... if ...) counts those that satisfy the equation. The line @lru_cache(maxsize=None) above the function is a **decorator**: it wraps the function so that a result, once computed for some n_2, is remembered and returned at once the next time.

```
RUST_MU = {r["id"]: float(r["mu"])
           for r in read_csv(f"{KS}/results/thermo/thermodynamics.csv")}
REFINEMENT = {s["id"]: s for s in read_json(f"{KS}/checker/rust-refinement.json")
              ["states"] if s["kind"] == "thermo"}
```

RUST_MU files the committed Rust chemical potentials of all thermal states under their ids (from the column mu of thermodynamics.csv). REFINEMENT files the thermal entries of the cross-check's measurement file rust-refinement.json; each holds, among other things, the final levels and degeneracies of the canonical Rust run, from which the checker computed its 40-digit roots.

```
def state_data(sid):
    """Everything this notebook needs about one thermal state, from the records."""
    rust = REFINEMENT[sid]  # the Rust run with the canonical numerics
    ref = read_json(f"{KS}/reference/results/thermo/{sid}.json")
    T, N = rust["canonical_T_N"]
    return {"id": sid, "T": T, "N": N,
            "eps_rust": np.array([e for e, g in rust["canonical_levels_eps_deg"]]),
            "g_rust": np.array([g for e, g in rust["canonical_levels_eps_deg"]]),
            "eps_ref": np.array(ref["levels"]["eps"]),
```

```
            "g_ref": np.array([4.0 * r3(k[0]) for k in ref["levels"]["keys"]]),
            "keys_ref": ref["levels"]["keys"],
            "U_levels_ref": max(ref["levels"]["U"]),  # largest level uncertainty
            "mu_rust": RUST_MU[sid], "mu_ref": ref["thermo"]["mu"]["value"],
            "U_mu_ref": ref["thermo"]["mu"]["U"]}
```

`state_data(sid)` collects everything the notebook needs about one thermal state: T and N; the Rust levels and degeneracies (two list comprehensions over the pairs (energy, degeneracy)); the reference levels from its result file, with the degeneracies computed as $4r_3(n_2)$ from each level's shell (`k[0]` is the first entry of the level's key); the keys; the largest level uncertainty of the reference; and the committed μ of both solvers with the reference's uncertainty of μ.

```
S = state_data(STATE)
print(" i  key (n2:j:parity:rank)   g   eps reference        eps Rust")
for i, key in enumerate(S["keys_ref"]):
    rust = f"{S['eps_rust'][i]:.15f}" if i < len(S["eps_rust"]) else "(not kept)"
    print(f"{i:2d}  {key[0]}:{key[1]:+d}:{key[2]}:{key[3]}"
          f"{'':12s}{S['g_ref'][i]:3.0f}   {S['eps_ref'][i]:.15f}   {rust}")
common = len(S["eps_rust"])  # the Rust label set keeps one level fewer
say(f"T = {S['T']}, N = {S['N']}; committed mu: Rust {S['mu_rust']!r}, reference "
    f"{S['mu_ref']!r}")
check(np.array_equal(S["g_rust"], S["g_ref"][:common])
      and np.max(np.abs(S["eps_rust"] - S["eps_ref"][:common])) < 1e-11,
      "both solvers have the same levels (to 1e-11) and degeneracies")
check(np.sum(S["g_rust"][S["eps_rust"] < 0.2]) == S["N"],
      "the eight particles exactly fill the two levels below the gap")
```

`S` holds the data of N8_lamm1_a00_T10. The table of Out [2] prints each reference level with its key, degeneracy and energy, and the Rust level next to it (the braces with an empty text and the format `12s` print twelve blanks; `{key[1]:+d}` prints the block type with its sign); the reference keeps one level more than the Rust solver (`"(not kept)"`). The first check requires the same degeneracies and levels that agree to 10^{-11}; they agree to about 10^{-12}. The second requires that the levels below 0.2 hold exactly the eight quanta: the two levels at 0.000245562708 with 4 states each.

```
checker_history = repository_file(f"{KS}/checker/README.md").read_text(
    encoding="utf-8")
found = re.search(r"Rust.s mu was ([0-9.]+) and the reference.s\s+([0-9.]+) "
                  r"\(\|diff\| ([0-9.e-]+) against a tolerance of ([0-9.e-]+)\)",
                  checker_history)
MU_OLD_RUST, MU_OLD_REF, DIFF_OLD, TOL_OLD = (float(x) for x in found.groups())
reference_history = repository_file(f"{KS}/reference/README.md").read_text(
    encoding="utf-8")
REF_OLD_MISS = float(re.search(r"this mu differed by ([0-9.e-]+) from the 40-digit",
                               reference_history).group(1))
say(f"history: Rust mu {MU_OLD_RUST!r}, reference mu {MU_OLD_REF!r}, |diff| "
    f"{DIFF_OLD:.3g}, tolerance {TOL_OLD:.3g}; reference first run missed its root "
    f"by {REF_OLD_MISS:.3g}")
check(abs(MU_OLD_RUST - MU_OLD_REF) - DIFF_OLD < 5e-13 and DIFF_OLD > TOL_OLD,
      "the recorded difference exceeds the recorded tolerance",
      record=f"{KS}/checker/README.md, History 1")
```

The numbers of the history are read from the two README files with regular expressions, so that the notebook uses the recorded values, not copies typed by hand. In the first pattern a point `.` matches any single character (here the apostrophe of the words "Rust's" and "reference's"), `\s+` one or more blanks or line breaks (the README breaks this sentence across two lines), `\(` and `\|` a literal bracket and vertical bar, and each `(...)` captures a number; `found.groups()` returns the four captured texts, which the **generator** `(float(x) for x in ...)` turns into four numbers given four names at once. The second pattern reads how far the reference's first complete run missed its own root. Out [2] prints the history: Rust $\mu = 0.2100104489071649$, reference $\mu = 0.2100104497343054$, difference 8.27×10^{-10}, tolerance 7.97×10^{-12}; the reference's first run missed its root by 1.15×10^{-9}. The check confirms that the recorded difference is the difference of the two recorded values (to 5×10^{-13}, the rounding of the printed digits) and exceeds the tolerance.

In [3], the state as a picture (Figure 16c.1).

```
sys.dont_write_bytecode = True  # do not write a __pycache__ folder into the record
sys.path.insert(0, str(repository_file(f"{KS}/reference")))  # Python looks here too
import ks_fd as K  # noqa: E402  the reference solver's module (Revision code)
```

The reference module `ks_fd` is imported as `K`, as in Notebook 16b.

```
eps, g, T, N = S["eps_ref"], S["g_ref"], S["T"], S["N"]
mu = S["mu_ref"]
x = (eps - mu) / T
below = eps < mu
holes = g * K.fermi(-x)  # g (1 - f): f(-x) = 1 - f(x), computed without subtracting
particles = g * K.fermi(x)  # g f
```

With the reference levels and committed μ, `x` holds the arguments $(\varepsilon_i - \mu)/T$ and `below` marks the levels below μ. `K.fermi` is the reference's Fermi function; it computes $e^{-|x|}$ first and returns $e^{-|x|}/(1+e^{-|x|})$ for $x > 0$ and $1/(1+e^{-|x|})$ otherwise, so it never computes the exponential of a large positive number, which would overflow. `holes` are $g(1-f) = g\,f(-x)$, computed directly as $f(-x)$ and never as a subtraction $1 - f$ (which would lose all digits for a full level), and `particles` are $g\,f$.

```
fig, (left, right) = plt.subplots(1, 2, figsize=(10.5, 4.2))
energies = np.linspace(-0.05, 1.0, 2001)
left.plot(energies, K.fermi((energies - mu) / T), color=PALETTE[0], lw=1.8,
          label="occupation $f((\\varepsilon - \\mu)/T)$")
for e in np.unique(eps):  # one dotted line per energy, labelled with its states
    left.axvline(e, color="k", lw=0.8, ls=":")
    states = g[eps == e]
    label = (f"g = {states[0]:.0f}" if len(states) == 1
             else f"{len(states)} levels, g = {states[0]:.0f} each")
    left.text(e + 0.008, 0.08, label, rotation=90, fontsize=8)
left.axvline(mu, color=PALETTE[1], lw=1.4, ls="--", label=f"$\\mu = {mu:.6f}$")
left.annotate("", (eps[2], 1.12), (eps[1], 1.12), arrowprops={"arrowstyle": "<->"})
left.text(0.5 * (eps[1] + eps[2]), 1.15, "gap $= 43\\,T$", ha="center")
left.set_ylim(-0.05, 1.25)
left.set_xlabel("energy $\\varepsilon$ (units of $m$)")
```

```
left.set_ylabel("occupation $f$")
left.set_title("N8_lamm1_a00_T10: levels and occupation")
left.legend(fontsize=8, loc="center right", framealpha=1.0)
```

The left panel draws the occupation $f((\varepsilon-\mu)/T)$ on 2001 energies from -0.05 to 1, a dotted vertical line at each distinct level (`np.unique`), labelled with its degeneracy, turned by 90 degrees (two levels share the lowest energy, so their label says "2 levels, g = 4 each"), μ as a dashed orange line, and a double arrow over the gap between the levels number 1 and 2 with the text "gap = $43\,T$".

```
right.semilogy(eps[below], holes[below], "v", color=PALETTE[1], ms=9,
               label=f"holes $g(1-f)$, sum {np.sum(holes[below]):.3e}")
right.semilogy(eps[~below], particles[~below], "^", color=PALETTE[0], ms=9,
               label=f"particles $g f$, sum {np.sum(particles[~below]):.3e}")
right.axvline(mu, color=PALETTE[1], lw=1.4, ls="--")
right.set_xlabel("energy $\\varepsilon$ (units of $m$)")
right.set_ylabel("thermal holes and particles")
right.set_title("the balance that fixes $\\mu$")
right.legend(fontsize=8, loc="upper right")
fig.tight_layout()
```

The right panel draws the holes of the levels below μ (triangles pointing down) and the particles of the levels above it (triangles up) on a logarithmic axis, with their sums in the legend.

```
save_figure(fig, "levels_and_occupations",
            "The thermal Kohn-Sham state N8_lamm1_a00_T10 ($N = 8$, $\\lambda = "
            "-\\lambda_1$, $a_{4,0} = 0$, $T = 0.01\\,m$) of the reference solver. "
            "Left: the Fermi-Dirac occupation against the energy in units of $m$, "
            "with the levels as dotted lines and their degeneracies $g$; the two "
            "lowest levels hold the eight particles, the next level lies 43 times "
            "$T$ higher, and $\\mu$ (dashed) sits in the middle of this gap. Right: "
            "the thermal holes of the full levels and the thermal particles of the "
            "empty ones on a logarithmic axis; both sums are about $6 \\times "
            "10^{-9}$ and cancel, which is the Mermin condition.")
```

`save_figure` saves Figure 16c.1. What the student should see: on the left, the occupation is a step from 1 to 0 about $T = 0.01$ wide, centred at $\mu = 0.210010$, in the middle of a gap 43 times wider; the two lowest levels lie at the top of the step, all others at the bottom. On the right, the holes of the lowest levels and the particles of the level at 0.43 are both about 6×10^{-9}; the particles of the higher levels fall off steeply (10^{-15}, 10^{-20}, ...), because each level's particles shrink by $e^{-\Delta\varepsilon/T}$.

```
balance = np.sum(holes[below]) - np.sum(particles[~below])
say(f"holes {np.sum(holes[below]):.6e}, particles {np.sum(particles[~below]):.6e}, "
    f"difference {balance:.2e}")
check(abs(balance) < 1e-15 and np.sum(g[below]) == N,
      "at the committed mu the thermal holes and particles balance (to 1e-15)")
```

`balance` is the holes minus the particles; Out [3] prints both, 6.210359×10^{-9}, and their difference, -6.6×10^{-24}. The check requires a balance below 10^{-15} and the levels below μ to hold exactly N states: the Mermin condition in the form $P = H_{th}$ of Section 16.20.

In [4], the root with 40 digits: Newton's method.

```
mp.mp.dps = 40  # every mpmath number now carries 40 significant digits
```

`mp.mp.dps = 40` sets the working precision of mpmath to 40 decimal places (significant digits) for every following computation.

```
def mermin_root_40(eps, g, N, T, start):
    """Newton's method for the root mu of sum g f((eps - mu)/T) = N with 40 digits.
    Returns (the root, dN/dmu there, the list of all guesses)."""
    E = [mp.mpf(float(e)) for e in eps]  # the levels, exactly the given doubles
    G = [mp.mpf(float(x)) for x in g]
    T40, N40, mu = mp.mpf(float(T)), mp.mpf(float(N)), mp.mpf(float(start))
    guesses = [mu]
    for _ in range(60):
        total, slope = mp.mpf(0), mp.mpf(0)
        for e, gi in zip(E, G):
            x = (e - mu) / T40
            if x > 2000:  # f < e^(-2000): invisible even with 40 digits
                continue
            f = 1 / (1 + mp.exp(x))
            total += gi * f  # N(mu)
            slope += gi * f * (1 - f) / T40  # dN/dmu
        step = (total - N40) / slope  # where the tangent line reaches N
        mu -= step
        guesses.append(mu)
        if abs(step) < mp.mpf(10) ** -32:  # the first 32 digits are settled
            break
    return mu, slope, guesses
```

`mermin_root_40` is Newton's method of Section 16.20 in 40-digit numbers. `mp.mpf(float(e))` turns each level into an mpmath number exactly equal to the given double (no digit is invented or lost). The loop makes at most 60 steps. In each it adds up $N(\mu)$ (`total`) and $N'(\mu) = \sum gf(1-f)/T$ (`slope`) over the levels, skipping levels with $x > 2000$, whose occupation e^{-2000} is invisible even with 40 digits. `step` is $(N(\mu) - N)/N'(\mu)$, and the new guess is μ minus the step; every guess is kept. The loop stops when a step is below 10^{-32} (`mp.mpf(10) ** -32`): then the first 32 digits are settled. The function returns the root, the slope there and all guesses.

```
start = 0.5 * (S["eps_rust"][1] + S["eps_rust"][2])  # the middle of the gap
ROOT_R, SLOPE_R, NEWTON_PATH = mermin_root_40(S["eps_rust"], S["g_rust"], 8, 0.01,
                                              start)
ROOT_F, SLOPE_F, _ = mermin_root_40(S["eps_ref"], S["g_ref"], 8, 0.01, start)
print("Newton steps from the middle of the gap (Rust levels):")
for k, guess in enumerate(NEWTON_PATH):
    distance = mp.nstr(abs(guess - ROOT_R), 3)  # from the final root
    print(f"  mu_{k} = {mp.nstr(guess, 34)}   distance {distance}")
report("40-digit root on the Rust levels", mp.nstr(ROOT_R, 30))
report("40-digit root on the reference levels", mp.nstr(ROOT_F, 30))
report("dN/dmu at the root (Rust levels)", mp.nstr(SLOPE_R, 7))
```

Newton's method starts in the middle of the gap, at $(\varepsilon_1 + \varepsilon_2)/2$ of the Rust levels (positions 1 and 2 of the list), and is run on the Rust and on the reference levels. The loop prints every guess with

34 digits and its distance from the final root (`mp.nstr(x, n)` writes x with n significant digits): the distances 5.49×10^{-3}, 4.93×10^{-4}, 3.99×10^{-7}, 2.12×10^{-16}, 1.48×10^{-34} and 0 show the doubling of the correct digits (Out [4]). The three RESULT lines give the two roots with 30 digits and $N' = 1.242072 \times 10^{-6}$.

```
fixture = next(s for s in read_json(f"{KS}/solver/tools/mermin-roots-40digit.json")
               ["fixture"] if s["id"] == STATE)
same_doubles = [float(e) for e, _ in fixture["levels"]] == list(S["eps_rust"])
check(same_doubles and abs(ROOT_R - mp.mpf(fixture["root40"])) < mp.mpf(10) ** -32,
      "the root on the Rust levels equals the fixture root40 to 1e-32",
      record=f"{KS}/solver/tools/mermin-roots-40digit.json, state {STATE}")
```

`fixture` is the entry of this state in the Rust solver's 40-digit fixture `mermin-roots-40digit.jso n`, made from the exact doubles of its final levels. `same_doubles` confirms that the fixture's levels are exactly our Rust levels, and the check requires our root to equal the fixture's `root40` to 10^{-32}.

```
sys.path.insert(0, str(repository_file(f"{KS}/checker")))
import crosscheck_ks as CC  # noqa: E402  the cross-check program (Revision code)

checker_root, _ = CC.mu_high_precision(list(S["eps_rust"]), list(S["g_rust"]), 8.0,
                                       0.01, S["mu_rust"])
row = {r["case"]: r for r in read_csv(f"{KS}/reports/ks-crosscheck-table.csv")}[
    f"{STATE} mu_high_precision"]
say(f"table row: Rust {row['rust']}, reference {row['reference']}, |diff| "
    f"{row['abs_diff']}; ours: |diff| {mp.nstr(abs(ROOT_R - ROOT_F), 4)}")
check(checker_root == float(ROOT_R) and abs(float(ROOT_R) - float(row["rust"])) < 1e-16
      and abs(float(ROOT_F) - float(row["reference"])) < 1e-16,
      "our 40-digit roots equal the checker's function and its table row",
      record=f"{KS}/reports/ks-crosscheck.json, check thermo_mu_high_precision")
```

The cross-check program `crosscheck_ks.py` is imported as `CC` (its folder is added to the search list first), and its own 40-digit function `mu_high_precision` computes the root on the Rust levels, starting from the committed μ. `row` is the row `N8_lamm1_a00_T10 mu_high_precision` of the cross-check table (a dictionary comprehension over all rows, then indexed by the case name). The printed line compares the table's two roots and their difference, 4.018×10^{-13}, with ours. The check requires our root, converted to a double, to equal the checker's exactly and both roots to equal the table's to 10^{-16}.

```
check(abs(abs(ROOT_R - ROOT_F) - mp.mpf(row["abs_diff"])) < 1e-16
      and abs(ROOT_R - ROOT_F) < 1e-12,
      "the two roots differ by only 4e-13: the levels agree, the old Rust mu did not")
```

The last check: our two roots differ by the table's 4.018×10^{-13} and by less than 10^{-12}. The levels of the two solvers agree; the old Rust μ, 8.3×10^{-10} below both roots, did not.

In [5], why 16 digits are not enough: the staircase.

```
eps_r, g_r = S["eps_rust"], S["g_rust"]
```

```
def direct_residual(mu, eps, g, N, T):
    """sum g f - N, added up directly in doubles (the method of the first runs)."""
    return float(np.sum(g * K.fermi((eps - mu) / T))) - N

def exact_residual(mu40, eps, g, N, T):
    """sum g f - N with 40 digits (mu40 an mpmath number)."""
    return sum(mp.mpf(float(gi)) / (1 + mp.exp((mp.mpf(float(e)) - mu40) / T))
               for e, gi in zip(eps, g)) - N
```

`direct_residual` is the residual $\sum gf - N$ added up directly in doubles, the method of the first runs (`np.sum` of the products, `float` to make it an ordinary number). `exact_residual` is the same sum in 40-digit numbers, for a 40-digit μ.

```
shifts = np.linspace(-3e-9, 3e-9, 1201)  # distances from the root, units of m
mu_star = float(ROOT_R)  # the double nearest to the 40-digit root
D = np.array([direct_residual(mu_star + d, eps_r, g_r, 8.0, 0.01) for d in shifts])
W = np.array([K.mermin_residual(eps_r, g_r, 8.0, 0.01, mu_star + d) for d in shifts])
X = np.array([float(exact_residual(mp.mpf(mu_star) + mp.mpf(float(d)), eps_r, g_r,
                                   8, mp.mpf("0.01"))) for d in shifts])
steps = np.unique(D)  # the different values the direct residual takes
zero = shifts[D == 0.0]  # where the computed direct residual is exactly zero
```

`shifts` holds 1201 distances from the root between -3×10^{-9} and 3×10^{-9}, 5×10^{-12} apart. `mu_star` is the double nearest to the 40-digit root. At each shifted μ the cell evaluates the direct residual `D`, the well-conditioned residual `W` of Section 16.20 with the reference's function `K.mermin_residual`, and the exact residual `X` with 40 digits (the shift is added in 40-digit numbers, and the temperature is given as the exact text `"0.01"`). `steps` holds the different values that `D` takes (`np.unique` sorts them and removes repetitions), and `zero` the shifts at which `D` is exactly zero.

```
say(f"the direct residual takes {len(steps)} different values in this window: "
    + ", ".join(f"{v / 2.0 ** -50:+.0f}" for v in steps) + " times 2^-50")
say(f"it is exactly zero for mu - root from {zero.min():.3e} to {zero.max():.3e}, "
    f"an interval {zero.max() - zero.min():.2e} wide")
say(f"largest |W - exact| = {np.max(np.abs(W - X)):.1e}, largest |D - exact| = "
    f"{np.max(np.abs(D - X)):.1e}")
check(np.all(np.mod(D / 2.0 ** -50, 1.0) == 0.0) and len(steps) <= 12,
      "the direct residual is a staircase: whole multiples of 2^-50 only")
check(3e-10 < zero.max() - zero.min() < 3e-9,
      "the direct residual vanishes on an interval about 1e-9 wide")
check(np.max(np.abs(W - X)) < 1e-20,
      "the well-conditioned residual follows the exact one to 1e-20")
```

Out [5]: the direct residual takes only six values in this window, -4, -3, -2, 0, $+2$ and $+4$ times 2^{-50}. Above 8 it moves in steps of $2^{-49} = 2 \cdot 2^{-50}$, the spacing of the doubles there (Section 16.20). Below 8 it moves in steps of one spacing, 2^{-50}, except at the last step: the value $-1 \cdot 2^{-50}$, that is the sum $8 - 2^{-50}$, never occurs in this window, and the residual jumps from -2 straight to 0 times 2^{-50}. Which doubles the computed sum can reach is decided by the rounding of the individual terms and of the partial sums along the way, not only by the spacing near 8; this is also why the

zero interval is not centred on the root. It is exactly zero from 8.250×10^{-10} below the root to 2.300×10^{-10} above it, an interval 1.05×10^{-9} wide (the estimate of Section 16.20 is 1.07×10^{-9}). The well-conditioned residual differs from the exact one by at most 3.9×10^{-23}, the direct one by up to 1.5×10^{-15}. The three checks require: every value of `D` a whole multiple of 2^{-50} (`np.mod(x, 1.0)` is the fractional part) and at most 12 different values; a zero interval between 3×10^{-10} and 3×10^{-9} wide; and `W` within 10^{-20} of the exact residual.

In [6], the staircase as a picture (Figure 16c.2).

```
fig, ax = plt.subplots(figsize=(8.5, 5.0))
scale_mu, scale_r = 1e-9, 1e-15  # plot units: 1e-9 m and 1e-15 particles
ax.axvspan(zero.min() / scale_mu, zero.max() / scale_mu, color="0.85",
           label="direct residual exactly 0")
ax.step(shifts / scale_mu, D / scale_r, where="mid", color=PALETTE[1], lw=1.8,
        label="direct residual $D$ in doubles")
ax.plot(shifts / scale_mu, W / scale_r, color=PALETTE[0], lw=2.5, alpha=0.8,
        label="well-conditioned residual $W$ in doubles")
ax.plot(shifts / scale_mu, X / scale_r, "k--", lw=1.0, label="exact (40 digits)")
ax.axvline((MU_OLD_RUST - mu_star) / scale_mu, color=PALETTE[7], lw=1.5,
           label="mu of the first cross-check (Rust)")
ax.axhline(0.0, color="k", lw=0.6)
ax.set_xlabel("$\\mu$ minus the 40-digit root (units of $10^{-9}\\,m$)")
ax.set_ylabel("$N(\\mu) - N$ (units of $10^{-15}$)")
ax.set_title("N8_lamm1_a00_T10: the computed residual near the root")
ax.legend(fontsize=8, loc="upper left")
```

The plot units are 10^{-9} for μ and 10^{-15} for the residual. `axvspan` shades the zero interval in light grey (the colour `"0.85"` is a grey level). `ax.step(..., where="mid")` draws the direct residual as a staircase whose steps change half-way between the sample points; the well-conditioned residual is a thick blue line and the exact one a thin dashed black line. A red vertical line marks the faulty μ of the first cross-check, measured from the root.

```
save_figure(fig, "residual_staircase",
            "The residual $N(\\mu) - N$ of the Mermin condition of the state "
            "N8_lamm1_a00_T10 (Rust levels) within $3 \\times 10^{-9}\\,m$ of the "
            "40-digit root, horizontal axis in units of $10^{-9}\\,m$, vertical axis "
            "in units of $10^{-15}$ particles. Added up directly in ordinary computer "
            "numbers (orange) the sum near 8 can only change in steps of $2^{-50}$ "
            "or $2^{-49}$, so the residual is a staircase that is exactly zero on an "
            "interval about $10^{-9}$ wide (grey); the faulty $\\mu$ of the first "
            "cross-check (red) is the left end of that interval. The "
            "well-conditioned form (blue) follows the exact line (dashed) and "
            "crosses zero at the root.")
```

`save_figure` saves Figure 16c.2. What the student should see: the exact residual is a straight line through zero at the root, with slope $N' = 1.24 \times 10^{-6}$ (in these units 1.24 per unit); the blue well-conditioned residual lies on it everywhere; the orange direct residual is a staircase with steps of $2^{-50} = 0.89$ and $2^{-49} = 1.78$ units, exactly zero on the grey interval; and the red line, the faulty μ, is the left end of that interval, where bisection on the direct sum must stop.

In [7], bisection on the two forms: the faulty value and the repair.

```
def bisection(residual, lo, hi):
    """Bisection for the root of an increasing function with residual(lo) < 0 and
    residual(hi) >= 0, down to neighbouring doubles; returns (root, all midpoints)."""
    midpoints = []
    while True:
        mid = 0.5 * (lo + hi)
        if mid <= lo or mid >= hi:  # lo and hi are neighbouring doubles: done
            break
        midpoints.append(mid)
        if residual(mid) < 0.0:
            lo = mid  # the root lies above mid
        else:
            hi = mid  # the root lies at or below mid
    return 0.5 * (lo + hi), midpoints
```

`bisection(residual, lo, hi)` is the bisection of Section 16.20 for an increasing function given as an argument (in Python a function can be passed like any other value). The `while True:` loop runs until `break`: if the midpoint is not strictly between `lo` and `hi`, the two are neighbouring doubles and nothing is left to halve. Otherwise the midpoint is recorded, and the half is kept in which the root lies: above the midpoint if the residual is negative there, at or below it otherwise.

```
def bracket(eps, T):
    """The starting interval of the reference: every level, 60 T and 1 m around."""
    return float(eps.min()) - 60.0 * T - 1.0, float(eps.max()) + 60.0 * T + 1.0
```

`bracket` gives the starting interval that the reference uses: from the lowest level minus $60T$ minus 1 to the highest level plus $60T$ plus 1, which surely contains the root.

```
MU_DIRECT, PATH_DIRECT = bisection(
    lambda mu: direct_residual(mu, eps_r, g_r, 8.0, 0.01), *bracket(eps_r, 0.01))
MU_WELL, PATH_WELL = bisection(
    lambda mu: K.mermin_residual(eps_r, g_r, 8.0, 0.01, mu), *bracket(eps_r, 0.01))
_, mu_ks_fd = K.mermin(eps_r, g_r, 8.0, 0.01)  # the reference's own function
say(f"bisection, direct sum:      mu = {MU_DIRECT!r} after {len(PATH_DIRECT)} "
    f"halvings; minus root {float(MU_DIRECT - ROOT_R):+.3e}")
say(f"bisection, well-conditioned: mu = {MU_WELL!r} after {len(PATH_WELL)} "
    f"halvings; minus root {float(MU_WELL - ROOT_R):+.3e}")
say(f"recorded mu of the first cross-check (Rust): {MU_OLD_RUST!r}; committed "
    f"repaired Rust mu: {S['mu_rust']!r}")
report("direct-sum bisection minus the 40-digit root",
       f"{float(MU_DIRECT - ROOT_R):.4e}", "m")
```

The two bisections on the Rust levels: on the direct residual and on the well-conditioned one (each residual is given as a lambda of μ alone). `K.mermin` is the reference's own root finder, which bisects the well-conditioned form. Out [7]: the direct sum gives $\mu = 0.21001044890716491$, 8.267×10^{-10} below the root, and the well-conditioned form 0.21001044973390365, 2.6×10^{-18} from it; both after 57 halvings. That number is no accident: the starting interval reaches from -1.600 to 2.482, so it is 4.08 wide; the doubles near 0.21 are $2^{-55} = 2.8 \times 10^{-17}$ apart; and $4.08/2^{57} = 2.8 \times 10^{-17}$, so after 57 halvings `lo` and `hi` are neighbouring doubles. The RESULT line repeats the error of the direct sum.

```
check(abs(MU_DIRECT - MU_OLD_RUST) <= 5e-17,
      "bisection on the direct sum gives the recorded faulty mu (all 16 digits)",
      record=f"{KS}/checker/README.md, History 1 (Rust mu 0.2100104489071649)")

check(abs(S["mu_rust"] - MU_WELL) < 1e-16,
      "the committed repaired Rust mu equals the well-conditioned root",
      record=f"{KS}/results/thermo/thermodynamics.csv, state {STATE}")
```

The three checks: the direct-sum bisection reproduces the recorded faulty $\mu = 0.2100104489071649$ of the first cross-check to 5×10^{-17}, that is, in all sixteen digits that the record prints; the well-conditioned bisection gives exactly the result of the reference's own function and lies within 10^{-16} of the root; and the committed, repaired Rust μ equals the well-conditioned root to 10^{-16}.

```
mu_direct_ref, _ = bisection(
    lambda mu: direct_residual(mu, S["eps_ref"], S["g_ref"], 8.0, 0.01),
    *bracket(S["eps_ref"], 0.01))
say(f"the direct sum on the reference levels misses their root by "
    f"{float(mu_direct_ref - ROOT_F):+.3e}")
```

The direct sum on the reference levels misses their own root by almost the same amount, 8.271×10^{-10}: the two level sets agree to about 10^{-12}, so their staircases have zero intervals at almost the same place, and bisection stops at the left end again.

In [8], three searches compared (Figure 16c.3).

```
fig, ax = plt.subplots(figsize=(8.5, 5.0))
floor = 1e-36  # distances that are exactly zero are drawn here
for colour, path, label, size in (
        (PALETTE[0], PATH_WELL, "bisection, well-conditioned form", 6),
        (PALETTE[1], PATH_DIRECT, "bisection, direct sum", 3)):  # drawn on top
    distance = [max(float(abs(mp.mpf(m) - ROOT_R)), floor) for m in path]
    ax.semilogy(range(1, len(path) + 1), distance, "o-", color=colour, ms=size,
                lw=1.2, label=f"{label} ({len(path)} steps)")
newton = [max(float(abs(m - ROOT_R)), floor) for m in NEWTON_PATH]
ax.semilogy(range(len(newton)), newton, "s-", color=PALETTE[2], ms=6, lw=1.5,
            label="Newton with 40 digits")
```

For the two bisections the distance of every midpoint from the 40-digit root is drawn against the step number on a logarithmic axis (distances that are exactly zero are raised to 10^{-36}); the direct-sum path is drawn second, with smaller markers, so that it lies on top. The Newton guesses are drawn as green squares.

```
ax.axhline(abs(MU_OLD_RUST - float(ROOT_R)), color=PALETTE[7], lw=1.0, ls="--",
           label="error of the first cross-check")
ax.axhline(math.ulp(mu_star), color="k", lw=0.8, ls=":",
           label="spacing of the doubles near $\\mu$")
ax.set_ylim(floor / 3.0, 10.0)
ax.set_xlabel("step")
ax.set_ylabel("distance from the 40-digit root (units of $m$)")
```

```
ax.set_title("Three searches for $\\mu$ in N8_lamm1_a00_T10")
ax.legend(fontsize=8, loc="upper right")
```

Two horizontal lines mark the error of the first cross-check (red, dashed) and the spacing of the doubles near μ (`math.ulp(x)` is the distance from x to the next double; dotted).

```
save_figure(fig, "convergence_paths",
            "The distance of each guess for $\\mu$ from the 40-digit root, units "
            "of $m$, logarithmic, against the step number, for the state "
            "N8_lamm1_a00_T10 with the Rust levels. Bisection halves the distance at "
            "every step; on the direct sum (orange) it stalls at $8.3 \\times "
            "10^{-10}$, the error of the first cross-check (red dashed), because "
            "the computed sum is zero on a whole interval; on the well-conditioned "
            "form (blue) it reaches the spacing of the doubles (dotted). Newton's "
            "method with 40 digits (green) doubles the number of correct digits at "
            "each step; zero distances are drawn at $10^{-36}$.")
check(min(float(abs(mp.mpf(m) - ROOT_R)) for m in PATH_DIRECT[-20:]) > 5e-10
      and float(abs(NEWTON_PATH[-2] - ROOT_R)) < 1e-32 and len(NEWTON_PATH) <= 7,
      "the direct bisection stalls above 5e-10; Newton reaches 1e-32 in 5 steps")
```

`save_figure` saves Figure 16c.3. What the student should see: the two bisection paths coincide for about 30 steps, halving the distance at every step on average (a straight line on this axis); then the direct-sum path stops falling and stays at 8.3×10^{-10} (it now only explores the zero interval of the staircase), while the well-conditioned path continues down to the spacing of the doubles; Newton's method with 40 digits reaches 10^{-34} in four steps. The check requires the last 20 direct-sum midpoints to stay more than 5×10^{-10} from the root, Newton's next-to-last guess to be within 10^{-32}, and at most 7 Newton guesses.

In [9], the rounding bounds.

```
def rounding_bounds(eps, g, N, T, mu):
    """dN/dmu, the bound of the direct sum and the bound of the well-conditioned form
    at mu (the formulas of solver/src/mermin.rs), and P, H_th, d."""
    x = (eps - mu) / T
    f_plus, f_minus = K.fermi(x), K.fermi(-x)  # f(x) and 1 - f(x) = f(-x)
    weight = g * f_plus * f_minus  # g f (1 - f): how strongly a level reacts to mu
    slope = float(np.sum(weight)) / T  # dN/dmu
    mean_distance = float(np.sum(weight * np.abs(eps - mu)) / np.sum(weight))
    below = x < 0.0
    particles = float(np.sum(g[~below] * f_plus[~below]))  # P
    holes = float(np.sum(g[below] * f_minus[below]))  # H_th
    d = N - float(np.sum(g[below]))  # a whole number
    n = len(eps)
    big_l = max(abs(math.log(particles + max(-d, 0.0))),  # |ln A|
                abs(math.log(holes + max(d, 0.0))))  # |ln B|
    common = EPS_MACH * (3.0 * mean_distance + T * (math.log(float(np.max(g))) + 3.0)
                         + 2.0 * abs(mu))
    direct = EPS_MACH * (n + 2) * N / slope + common
    well = EPS_MACH * (n + 2 + big_l) * (particles + holes + abs(d)) / slope + common
    return {"slope": slope, "direct": direct, "well": well, "P": particles,
            "H_th": holes, "d": d, "n": n, "Lambda": big_l}
```

`rounding_bounds` evaluates the two bounds of Section 16.20 at a given μ. `f_plus` and `f_minus` are $f(x)$ and $f(-x) = 1 - f(x)$; `weight` is $g\,f(1-f)$, how strongly each level reacts to μ; `slope` is $N' = \sum g f(1-f)/T$; `mean_distance` is $\langle|\varepsilon - \mu|\rangle$, the mean distance of the levels from μ weighted with `weight`. `particles` is P (the levels above μ; `~below` reverses the mask), `holes` is H_{th}, and `d` the whole number $N - \sum_{\text{below}} g$. `big_l` is $\Lambda = \max(|\ln A|, |\ln B|)$ with $A = P + \max(-d, 0)$ and $B = H_{th} + \max(d, 0)$, the two sides of the balance. `common` holds the three small terms that both bounds share, and `direct` and `well` are B_{direct} and B_{well}.

```
MERMIN_REPORT = read_json(f"{KS}/reports/ks-rust-mermin-roots.json")
RECORD = {s["id"]: s for s in MERMIN_REPORT["states"]}
b = rounding_bounds(eps_r, g_r, 8.0, 0.01, mu_star)
rec = RECORD[STATE]
say(f"n = {b['n']} levels; P = {b['P']:.6e}, H_th = {b['H_th']:.6e}, d = {b['d']:.0f}, "
    f"Lambda = {b['Lambda']:.3f}; dN/dmu = {b['slope']:.6e} (record {rec['dN_dmu']})")
say(f"B_direct = {b['direct']:.4e} (record {rec['boundDirectCount']}); B_well = "
    f"{b['well']:.4e} (record {rec['boundWellConditioned']})")
```

`MERMIN_REPORT` is the Rust solver's 40-digit report `ks-rust-mermin-roots.json`, and `RECORD` files its states by id. The bounds are evaluated at the double nearest to the root, and Out [9] prints them next to the record: $n = 7$ levels, $P = H_{th} = 6.210359 \times 10^{-9}$, $d = 0$, $\Lambda = 18.897$ (which is $|\ln(6.21 \times 10^{-9})|$), $N' = 1.242072 \times 10^{-6}$ (record the same), $B_{direct} = 1.2871 \times 10^{-8}$ (record 1.287×10^{-8}) and $B_{well} = 3.1539 \times 10^{-16}$ (record 3.154×10^{-16}).

```
one_step = EPS_MACH * 8.0 / b["slope"]  # one rounding of size eps_mach N, as mu
say(f"one rounding of size eps_mach N moves the root by {one_step:.3e}; the error "
    f"of the first cross-check is {DIFF_OLD / one_step:.2f} of that")
```

`one_step` is the shift $\epsilon_{mach} N/N' = 1.430 \times 10^{-9}$ that a single rounding of the size $\epsilon_{mach} N$ causes; the error of the first cross-check is 0.58 of it (Out [9]).

```
check(abs(b["slope"] / float(rec["dN_dmu"]) - 1) < 1e-5
      and abs(b["direct"] / float(rec["boundDirectCount"]) - 1) < 1e-3
      and abs(b["well"] / float(rec["boundWellConditioned"]) - 1) < 1e-3,
      "dN/dmu and both rounding bounds reproduce the Rust 40-digit report",
      record=f"{KS}/reports/ks-rust-mermin-roots.json, state {STATE}")
check(abs(MU_OLD_RUST - float(ROOT_R)) <= b["direct"]
      and abs(S["mu_rust"] - float(ROOT_R)) <= b["well"] + 1e-16,
      "the old error lies within B_direct, the repaired mu within B_well")
```

The first check reproduces the record: N' to a relative 10^{-5} and both bounds to 10^{-3} (the report prints four digits). The second confirms that the old error lies within B_{direct} and the repaired μ within B_{well}.

In [10], all 45 thermal states with eight quanta.

```
TABLE = {r["case"]: r for r in read_csv(f"{KS}/reports/ks-crosscheck-table.csv")}

def tolerance(x_ref, u_ref, u_rust):
    """The tolerance rule of the cross-check for single numbers."""
    return 3.0 * (u_ref + u_rust) + 1e-12 * max(1.0, abs(x_ref))
```

TABLE files the rows of the cross-check table by case, and tolerance is the rule of Section 16.7 for single numbers.

```
ROWS = []  # one dictionary per state
for sid in sorted(s for s in REFINEMENT if s.startswith("N8_")):
    s = state_data(sid)
    N, T = s["N"], s["T"]
    root_r, _, _ = mermin_root_40(s["eps_rust"], s["g_rust"], N, T, s["mu_rust"])
    root_f, _, _ = mermin_root_40(s["eps_ref"], s["g_ref"], N, T, s["mu_ref"])
    r = {"id": sid, "N": N, "T": T, "root_r": root_r, "root_f": root_f,
         "b_r": rounding_bounds(s["eps_rust"], s["g_rust"], N, T, float(root_r)),
         "b_f": rounding_bounds(s["eps_ref"], s["g_ref"], N, T, float(root_f))}
```

The loop goes through the 45 thermal states whose id begins with N8 (startswith), sorted. For each it collects the data, computes the 40-digit roots on the Rust and on the reference levels (Newton's method, started from each solver's committed μ), and evaluates both bounds at both roots.

```
    for side in ("r", "f"):  # the two bisections on each solver's levels
        e, gg = (s["eps_rust"], s["g_rust"]) if side == "r" else (s["eps_ref"],
                                                                  s["g_ref"])
        root = float(r["root_" + side])
        r["direct_" + side] = bisection(
            lambda mu: direct_residual(mu, e, gg, N, T), *bracket(e, T))[0] - root
        r["well_" + side] = bisection(
            lambda mu: K.mermin_residual(e, gg, N, T, mu), *bracket(e, T))[0] - root
```

For each solver's levels (side is "r" for Rust and "f" for the reference) it runs bisection on the direct sum and on the well-conditioned form and stores each result minus the root ([0] takes the root from the returned pair). The lambdas are used immediately inside the loop, so each sees the current levels e and degeneracies gg.

```
    r["committed_r"] = float(mp.mpf(s["mu_rust"]) - root_r)
    r["committed_f"] = float(mp.mpf(s["mu_ref"]) - root_f)
    r["U_mu_ref"] = s["U_mu_ref"]
    u_lev_rust = 16.0 / 15.0 * REFINEMENT[sid]["levels"]["max_abs_diff"]
    u_mu_rust = 16.0 / 15.0 * REFINEMENT[sid]["scalars"]["mu"]["abs_diff"]
    tol_hp = tolerance(float(root_f), s["U_levels_ref"], u_lev_rust)
    tol_mu = tolerance(s["mu_ref"], s["U_mu_ref"], u_mu_rust)
    r["ratio_hp"] = float(abs(root_r - root_f)) / tol_hp
    r["ratio_mu"] = abs(s["mu_rust"] - s["mu_ref"]) / tol_mu
    r["tol_hp"], r["tol_mu"] = tol_hp, tol_mu
    r["n_r"], r["n_f"] = len(s["eps_rust"]), len(s["eps_ref"])
    ROWS.append(r)
```

committed_r and committed_f are the committed μ of each solver minus its 40-digit root. The cell then rebuilds two comparisons of the cross-check: the 40-digit roots, with U_{ref} the reference's largest level uncertainty and U_{Rust} $\frac{16}{15}$ times the largest canonical-minus-refined level difference (because μ is a weighted mean of the levels, its uncertainty is bounded by theirs: Revision/kohn_sham/checker/crosscheck_ks.py, comment before the 40-digit check), and the committed values of μ, with the reference's U of μ and $\frac{16}{15}|\mu_c - \mu_r|$; it keeps both tolerances and ratios and the numbers of levels.

```
print("the nine states with the largest direct-sum bound (Rust levels):")
print("state                 n   dN/dmu     B_direct   direct error  B_well")
for r in sorted(ROWS, key=lambda r: -r["b_r"]["direct"])[:9]:
    print(f"{r['id']:20s} {r['n_r']:3d}  {r['b_r']['slope']:.3e}  "
          f"{r['b_r']['direct']:.3e}  {r['direct_r']:+.3e}    {r['b_r']['well']:.3e}")
```

The table of Out [10] lists the nine states with the largest B_{direct} (Rust levels), sorted by it (`key=lamb da r: -...` sorts from the largest down): their number of levels, N', B_{direct}, the error of the direct sum and B_{well}. The three states at $a_{4,0} = 0$, $T = 0.01$ have $N' \approx 1.2 \times 10^{-6}$ and bounds near 10^{-8}; the next ones, at $a_{4,0} = 0.5$ or $T = 0.02$, have N' thousands of times larger and bounds below 10^{-11}.

In [11], the checks against the records.

```
worst = {"root": 0.0, "slope": 0.0, "bounds": 0.0, "hp": 0.0, "tol": 0.0,
         "ratio": 0.0}
for r in ROWS:
    rec = RECORD[r["id"]]
    worst["root"] = max(worst["root"], float(abs(r["root_r"] - mp.mpf(rec["root40"]))))
    worst["slope"] = max(worst["slope"],
                         abs(r["b_r"]["slope"] / float(rec["dN_dmu"]) - 1))
    worst["bounds"] = max(worst["bounds"],
                          abs(r["b_r"]["direct"] / float(rec["boundDirectCount"]) - 1),
                          abs(r["b_r"]["well"] / float(rec["boundWellConditioned"])
                              - 1))
    hp, mu_row = TABLE[f"{r['id']} mu_high_precision"], TABLE[f"{r['id']} mu"]
    worst["hp"] = max(worst["hp"], abs(float(r["root_r"]) - float(hp["rust"])),
                      abs(float(r["root_f"]) - float(hp["reference"])))
    worst["tol"] = max(worst["tol"], abs(r["tol_hp"] / float(hp["tolerance"]) - 1),
                       abs(r["tol_mu"] / float(mu_row["tolerance"]) - 1))
    worst["ratio"] = max(worst["ratio"], abs(r["ratio_hp"] - float(hp["ratio"])),
                         abs(r["ratio_mu"] - float(mu_row["ratio"])))
```

`worst` collects six largest differences: of our Rust roots from the report's `root40`; of N' and of the two bounds from the report (relative); of both 40-digit roots from the table's rows `mu_high_precision`; of our tolerances from the table's (relative); and of our ratios from the table's, for both rows of each state (`mu_high_precision` and `mu`).

```
say("largest differences from the records: " + ", ".join(
    f"{k} {v:.1e}" for k, v in worst.items()))
check(worst["root"] < 1e-16,
      "the 45 roots on the Rust levels reproduce root40 (to the 16-digit levels)",
      record=f"{KS}/reports/ks-rust-mermin-roots.json, states (root40)")
check(worst["slope"] < 1e-5 and worst["bounds"] < 1e-3,
      "dN/dmu and both bounds of all 45 states reproduce the Rust report",
      record=f"{KS}/reports/ks-rust-mermin-roots.json, states (bounds)")
check(worst["hp"] < 2e-16 and worst["tol"] < 1e-3 and worst["ratio"] <= 1e-4,
      "both 40-digit roots, tolerances and ratios reproduce 90 table rows",
      record=f"{KS}/reports/ks-crosscheck-table.csv, rows mu, mu_high_precision")
check(all(r["ratio_hp"] <= 1.0 and r["ratio_mu"] <= 1.0 for r in ROWS),
      "after the repair every mu comparison of the 45 states passes",
      record=f"{KS}/reports/ks-crosscheck.json, check thermo_state_functions")
```

Out [11] prints them: roots 2.8×10^{-17}, slope 4.5×10^{-7}, bounds 4.2×10^{-4}, table roots 5.6×10^{-17}, tolerances 3.9×10^{-4}, ratios 5.0×10^{-5}. The roots agree only to about 10^{-17}, not 10^{-35}, because the level files keep sixteen significant digits; the bounds and tolerances agree to the four digits the records print. The four checks reproduce the report (roots, then N' and bounds), the 90 table rows, and the cross-check's verdict that after the repair every comparison of μ in these 45 states passes.

```
diag_r = [abs(r["committed_r"]) / (r["n_r"] * EPS_MACH * r["N"] / r["b_r"]["slope"])
          for r in ROWS]
diag_f = [abs(r["committed_f"]) / (r["n_f"] * EPS_MACH * r["N"] / r["b_f"]["slope"]
                                   + 3.0 * r["U_mu_ref"]) for r in ROWS]
say(f"committed mu minus root, as a fraction of the diagnostic bound: Rust at most "
    f"{max(diag_r):.1e}, reference at most {max(diag_f):.1e}")
check(max(diag_r) <= 1.0 and max(diag_f) <= 1.0,
      "both solvers' committed mu lie within the rounding diagnostic",
      record=f"{KS}/reports/ks-crosscheck.json, check thermo_mu_rounding_diagnostic")
```

The diagnostic of the cross-check (`thermo_mu_rounding_diagnostic`): each committed μ minus the root on its own levels, divided by the conditioning bound $n\,\epsilon_{mach} N/N'$ (for the reference plus $3U$, because its μ combines three grids). Out [11]: at most 1.3×10^{-2} for Rust and 1.4×10^{-5} for the reference; the check requires at most 1.

```
check(all(abs(r["direct_" + s]) <= r["b_" + s]["direct"]
          and abs(r["well_" + s]) <= r["b_" + s]["well"] for r in ROWS
          for s in ("r", "f")),
      "in all 90 level sets each bisection lies within its own bound")
big = sorted(ROWS, key=lambda r: -abs(r["direct_r"]))[:3]
say("largest direct-sum errors: " + ", ".join(
    f"{r['id']} {r['direct_r']:+.2e}" for r in big))
check({r["id"] for r in big} == {"N8_lam0_a00_T10", "N8_lamm1_a00_T10",
                                 "N8_lamp1_a00_T10"},
      "the direct sum fails worst in the three states with the largest gap/T")
```

The next check confirms that in all 90 level sets (45 states, two solvers) each bisection lies within its own bound: the direct sum within B_{direct} and the well-conditioned form within B_{well}. `big` holds the three states with the largest direct-sum errors on the Rust levels, printed in Out [11] (-8.27×10^{-10}, $+2.72 \times 10^{-10}$, $+6.96 \times 10^{-11}$), and the last check requires them to be the three states at $a_{4,0} = 0$ and $T = 0.01$, where the gap is largest compared with T (a set `{...}` of ids is compared, so the order does not matter).

In [12], error against conditioning (Figure 16c.4).

```
scale = np.array([EPS_MACH * r["N"] / r["b_r"]["slope"] for r in ROWS])
scale_f = np.array([EPS_MACH * r["N"] / r["b_f"]["slope"] for r in ROWS])
fig, ax = plt.subplots(figsize=(8.0, 6.0))
low = 1e-19  # exact zeros are drawn here
series = [(scale, "direct_r", "o", PALETTE[1], "direct sum, Rust levels"),
          (scale_f, "direct_f", "s", PALETTE[7], "direct sum, reference levels"),
          (scale, "well_r", "o", PALETTE[0], "well-conditioned, Rust levels"),
          (scale_f, "well_f", "s", PALETTE[6], "well-conditioned, reference levels"),
          (scale, "committed_r", "^", PALETTE[2], "committed Rust mu")]
```

```
for xs, key, marker, colour, label in series:
    ys = np.maximum([abs(r[key]) for r in ROWS], low)
    ax.loglog(xs, ys, marker, color=colour, ms=5, alpha=0.8, label=label)
```

`scale` and `scale_f` hold the conditioning scale $\epsilon_{mach} N/N'$ of each state for the Rust and the reference levels. `series` lists five sets of points with their key, marker, colour and label; the loop draws each error (raised to 10^{-19} if exactly zero) against the conditioning scale on logarithmic axes.

```
line = np.array([1e-16, 1e-8])
ax.loglog(line, line, "k-", lw=1.0, label="error = $\\epsilon_{mach} N / N'$")
i_old = [r["id"] for r in ROWS].index(STATE)
ax.loglog([scale[i_old]], [DIFF_OLD], "*", color="k", ms=14,
          label="first cross-check (recorded)")
ax.set_xlabel("$\\epsilon_{mach} N / (dN/d\\mu)$ (units of $m$)")
ax.set_ylabel("$|\\mu$ computed $-$ 40-digit root$|$ (units of $m$)")
ax.set_title("45 thermal states with $N = 8$: error against conditioning")
ax.legend(fontsize=7, loc="upper left")
```

The black line is "error equals conditioning scale", a line of slope 1, and the star is the recorded error of the first cross-check at the scale of its state (`.index(STATE)` finds the state's position).

```
save_figure(fig, "errors_versus_bound",
            "Errors of the computed chemical potential, in units of $m$, against "
            "the conditioning scale $\\epsilon_{mach} N/(dN/d\\mu)$ for the 45 "
            "thermal states with $N = 8$, both axes logarithmic. Bisection on the "
            "direct sum (orange: Rust levels, red: reference levels) has errors "
            "that grow with the conditioning scale and approach the line of slope 1 "
            "in the worst states; the star is the recorded error of the first "
            "cross-check. The well-conditioned form (blue, purple) and the "
            "committed repaired Rust values (green) stay near $10^{-17}$ for every "
            "state; exact zeros are drawn at $10^{-19}$.")
```

`save_figure` saves Figure 16c.4. What the student should see: the errors of the direct sum (orange and red) grow with the conditioning scale and come within a factor of about 2 of the line of slope 1 in the worst states, where the star of the first cross-check sits; the well-conditioned form (blue, purple) and the committed repaired Rust values (green) stay near 10^{-17} whatever the conditioning, many of them exactly zero (the bottom row).

In [13], where the direct sum is dangerous (Figure 16c.5).

```
tags = [("lam0", "$\\lambda = 0$"), ("lamp1", "$\\lambda = +\\lambda_1$"),
        ("lamm1", "$\\lambda = -\\lambda_1$")]
slices, temps = ["a00", "a05", "a10", "a15", "a20"], ["T10", "T20", "T50"]
by_id = {r["id"]: r for r in ROWS}
fig, axes = plt.subplots(1, 3, figsize=(11.0, 4.6))
for ax, (tag, title) in zip(axes, tags):
    grid = np.array([[math.log10(by_id[f"N8_{tag}_{a}_{t}"]["b_r"]["direct"])
                      for t in temps] for a in slices])
    image = ax.imshow(grid, cmap="viridis", vmin=-15.0, vmax=-7.5, aspect="auto")
    ax.grid(False)  # no grid lines across the coloured squares
```

`tags` pairs the three coupling tags with their titles, `slices` and `temps` list the id parts of the five slices and three temperatures, and `by_id` files the 45 rows by id. For each coupling, `grid` is a 5×3 table of $\log_{10} B_{direct}$, slices down, temperatures across, built by a nested list comprehension; `imshow` paints it with the colour scale `viridis` between -15 and -7.5, and `ax.grid(False)` removes the grid lines over the squares.

```
    for i in range(5):
        for j in range(3):
            ax.text(j, i, f"{grid[i, j]:.1f}", ha="center", va="center",
                    color="w" if grid[i, j] < -11.5 else "k", fontsize=9)
    ax.set_xticks(range(3))
    ax.set_xticklabels(["0.01", "0.02", "0.05"])
    ax.set_yticks(range(5))
    ax.set_yticklabels(["0", "0.5", "1", "1.5", "2"])
    ax.set_xlabel("temperature $T$ (units of $m$)")
    ax.set_title(title)
axes[0].set_ylabel("slice $a_{4,0}$")
fig.colorbar(image, ax=axes, shrink=0.9, label="$\\log_{10} B_{direct}$ (units of $m$)")
```

Each square gets its number with one decimal, written in white on the dark squares and in black on the light ones; the ticks are labelled with the temperatures and the slices, and one colour scale serves the three maps.

```
save_figure(fig, "conditioning_map",
            "The rounding bound $B_{direct}$ of the direct sum, as $\\log_{10}$ of "
            "its value in units of $m$, for the 45 thermal states with $N = 8$ (Rust "
            "levels): one map per coupling, the slice $a_{4,0}$ of the deflating "
            "history downwards, the temperature across. The direct sum is dangerous "
            "only at low temperature early in the history, where the gap is 43 "
            "times $T$ and the bound reaches $10^{-8}$; later the redshift of the "
            "3-momenta closes the gap and the bound falls to about $10^{-15}$.")
check(max(by_id[f"N8_{t}_a00_T10"]["b_r"]["direct"] for t, _ in tags)
      == max(r["b_r"]["direct"] for r in ROWS)
      and all(by_id[f"N8_{t}_a00_T10"]["b_r"]["direct"]
              > 100.0 * by_id[f"N8_{t}_a10_T10"]["b_r"]["direct"] for t, _ in tags),
      "the bound is largest at a4,0 = 0, T = 0.01 and falls along the history")
```

`save_figure` saves Figure 16c.5. What the student should see: in each of the three maps only the top left square ($a_{4,0} = 0$, $T = 0.01$) is bright, at about -8, and its neighbours ($a_{4,0} = 0.5$ or $T = 0.02$) are near -11 to -12; everywhere else the bound lies between about 10^{-15} and 10^{-13}. Along the deflating history the gap closes, because the redshift of the 3-momenta brings the levels of the brane band down towards the filled levels. The check requires the largest bound of all 45 to be one of the three states at $a_{4,0} = 0$, $T = 0.01$, and each of them to be more than 100 times its value at $a_{4,0} = 1$.

In [14], what the tolerance rule did (Figure 16c.6).

```
order = sorted(range(len(ROWS)), key=lambda i: -ROWS[i]["b_r"]["direct"])
ratio_old = DIFF_OLD / TOL_OLD  # the ratio of the first, failed comparison
fig, ax = plt.subplots(figsize=(9.5, 4.8))
```

```
positions = np.arange(len(order))
ax.semilogy(positions, [ROWS[i]["ratio_mu"] for i in order], "o", color=PALETTE[0],
            ms=5, label="$\\mu$ (committed values), after the repair")
ax.semilogy(positions, [ROWS[i]["ratio_hp"] for i in order], "s", color=PALETTE[2],
            ms=5, mfc="none", label="$\\mu$ with 40 digits on each solver's levels")
k_old = order.index([r["id"] for r in ROWS].index(STATE))
ax.semilogy([k_old], [ratio_old], "*", color=PALETTE[7], ms=16,
            label=f"first cross-check, before the repair: {ratio_old:.0f}")
ax.axhline(1.0, color="k", lw=1.2, label="ratio 1: the tolerance")
```

`order` sorts the 45 states by B_{direct}, largest first, and `ratio_old` is the ratio of the failed first comparison, $8.27 \times 10^{-10} / 7.97 \times 10^{-12} = 103.8$. The ratios of the committed μ (circles) and of the 40-digit roots (open squares, `mfc="none"`) are drawn for each state in that order, the old ratio as a red star at the position of N8_lamm1_a00_T10, and the line ratio 1.

```
ax.set_xticks(positions[::4])
ax.set_xticklabels([ROWS[i]["id"].replace("N8_", "") for i in order][::4],
                   rotation=40, ha="right", fontsize=7)
ax.set_xlabel("state (sorted by the bound of the direct sum, largest first)")
ax.set_ylabel("$|\\mu_{Rust} - \\mu_{ref}|$ / tolerance")
ax.set_ylim(1e-4, 1e3)
ax.legend(fontsize=8, loc="upper right")
fig.tight_layout()
```

Every fourth state is named on the horizontal axis (without the common prefix N8_), and the vertical axis runs from 10^{-4} to 10^{3}.

```
save_figure(fig, "crosscheck_ratios",
            "The cross-check of the chemical potential for the 45 thermal states with "
            "$N = 8$: the difference of the two solvers divided by the tolerance "
            "fixed in advance, logarithmic, the states sorted by the rounding bound "
            "of the direct sum. Circles: the committed values after the repair; "
            "squares: the 40-digit roots on each solver's levels; all lie far below "
            "the line 1. The star is the first comparison in N8_lamm1_a00_T10, "
            f"before the repair, with the ratio {ratio_old:.0f}: the rule caught a "
            "rounding error of the Rust solver, and the repair, not a wider "
            "tolerance, removed it.")
```

`save_figure` saves Figure 16c.6. What the student should see: the star of the first comparison, at about 104, lies two orders of magnitude above the line 1; after the repair, the same rule gives ratios between about 5×10^{-4} and 0.08 for every state. The rule caught the error, and the repair, not a wider tolerance, removed it.

```
report_detail = next(c["detail"] for c in read_json(
    f"{KS}/reports/ks-crosscheck.json")["checks"]
    if c["name"] == "thermo_mu_high_precision")
worst_all = float(re.search(r"worst \|diff\|/tolerance ([0-9.]+)",
                            report_detail).group(1))
say(f"first comparison: ratio {ratio_old:.1f}. After the repair, over these 45 "
    f"states: mu at most {max(r['ratio_mu'] for r in ROWS):.4f}, 40-digit roots at "
```

```
    f"most {max(r['ratio_hp'] for r in ROWS):.4f} (the report, over all 135 states: "
    f"40-digit roots at most {worst_all})")
check(ratio_old > 1.0 and max(r["ratio_hp"] for r in ROWS) <= worst_all + 5e-4
      and max(r["ratio_mu"] for r in ROWS) < 0.1,
      "the first comparison failed the rule; after the repair all ratios are small",
      record=f"{KS}/reports/ks-crosscheck.json, check thermo_mu_high_precision")
```

The worst ratio of the 40-digit comparison over all 135 thermal states is read from the detail of the cross-check's check `thermo_mu_high_precision` (0.05). Out [14] prints the old ratio, 103.8, and the largest ratios over the 45 states after the repair: 0.0825 for the committed μ and 0.0270 for the 40-digit roots. The check requires the old ratio above 1, our 40-digit ratios no larger than the report's worst, and every ratio of the committed μ below 0.1.

In [15], the last check.

```
figure_files = [f"{FIGURE_FOLDER}/16c_{k}_{name}.png" for k, name in enumerate(
    ["levels_and_occupations", "residual_staircase", "convergence_paths",
     "errors_versus_bound", "conditioning_map", "crosscheck_ratios"], start=1)]
check(all(output_file(f).is_file() for f in figure_files),
      "every figure file of this notebook exists")
all_checks_passed()
```

As In [23] of Notebook 16a, for the six figures; it prints ALL 26 CHECKS PASSED (notebook 16c): seven checks in In [11], three each in In [2], In [4], In [5] and In [7], two in In [9], and one each in In [3], In [8], In [13], In [14] and In [15].

16.25 What the cross-check does not test

The cross-check is a test of the **numerics**: of the discretisation, the rounding and the programming of the Rust solver, against a second program that differs in all three. Everything that both programs take from the same source is outside its reach, and the record says so (`Revision/kohn_sham/reference/README.md`, the section on what the reference does not establish). Precisely:

- **The functional.** Both solvers read the same theory file `Revision/kohn_sham/ks-theory.json`: the contact interaction with Hartree and the exact local exchange of the uniform gas, and no correlation (Chapters 13 and 14). If that functional were a poor approximation for the field, both programs would agree on the wrong answer.
- **The boundary conditions.** Both use the ASSUMED Z2 mirror brane at $y = 0$ and the CHOSEN regular tip at the cutoff $y = -L$ with $L = 3$. The cross-check compares the two solvers at this same cutoff, so it cannot show how the results depend on L. That dependence is measured separately, in `Revision/kohn_sham/tip_convergence/` (report `tip-convergence.json`, 7 of 7 checks PASS): a copy of the Rust solver that reads L from the environment is run from $L = 3$ to 6 for 29 of the recorded states, and the reference solver, run for two of these states (N8_lamp1_a00 and N136_lam0_a20) at $L = 3$ and at $L = 4$, agrees with it in all 28 comparisons, seven quantities for each state and each L (the Kohn-Sham energy E_{KS}, the interaction energy, HOMO, LUMO and the integrals of p_0, n and ρ; check `reference_solver_at_two_L`). Its worst ratio, 0.005, is measured against that study's own tolerance

$10\,(U_{ref} + U_{Rust}) + 10^{-9}\max(1, |x|)$, which is looser than the rule of Section 16.7, so it cannot be compared with the 0.495 of the cross-check. The study finds that the recorded free results, except $N = 688$ at $a_{4,0} = 0$ (whose energy does not converge up to $L = 6$), lie within 1.4% (E_{KS}) and 12% (the energy-momentum integral of p_0) of their large-L values, while the interaction effects depend strongly on L: the recorded Kohn-Sham energy E_{KS} of the interacting states with $N = 8$ is about one third of its large-L value. Agreement of the two programs at $L = 3$ says nothing about these differences.

- **The filling convention.** Both fill only the positive branch and the brane zero modes and never populate the sea, not even thermally (a CONVENTION whose justification is OPEN). The sea-hole diagnostic, which both programs compute and which agree with each other (worst ratio 0.048), shows where this convention leaves its range of validity: in 15 of the 135 thermal states the excluded sea would carry more than 1% of N, at most $30.98N$ (`Revision/kohn_sham/reports/ks-crosscheck.json`, check `thermo_sea_hole_diagnostic`). Agreement of the two programs on this diagnostic says nothing about whether the convention is right.

- **The history and the adiabatic states.** Both compute instantaneous (adiabatic) Kohn-Sham states along the PRESCRIBED BACKGROUND history $a_4 = AHx_4$ with $A = 1$. The history is not solved for: the Kohn-Sham states violate the conditions that the a_4 field equations put on their source (`Revision/field_equations_a4/reports/ks-source-conditions.json`, Chapter 17), and the time-dependent (non-adiabatic) problem is OPEN.

- **The good sector.** Both assume that the quanta do not depend on the extra times x_5, x_6, x_7 (ASSUMED, Chapter 14).

Of these inputs, only the tip cutoff has been varied in a study of its own, and only in part: L from 3 to 6 for 29 recorded states in `Revision/kohn_sham/tip_convergence/` (above). Several of the other inputs are probed by diagnostics, which can show where an input fails but cannot confirm it: the filling convention by the sea-hole diagnostic and the prescribed history by the source conditions of the a_4 equations (both above), the exchange part of the functional by the exchange difference ΔE_x and the exact-Fock variant (Section 14.27), and the instantaneous (adiabatic) states by the adiabaticity measure Q_{max} and the search for Fermi-level crossings (Section 15.21). Even for the tip cutoff the large-L limit is not established for $N = 688$ at $a_{4,0} = 0$, nor for the 7 interacting states whose self-consistent iteration fails before the successive differences of E_{KS} meet that study's rule for a geometric tail, nor, in 8 further interacting states, for some quantities other than E_{KS} (the interaction energy and the integrals of p_3 and p_t among them). A test that could confirm the other inputs would need something other than a second program for the same equations: an exact functional for the quantised field, a justification or a replacement of the filling convention, a solution of the coupled problem for a_4 and the gas, a time-dependent calculation. These are OPEN problems (Chapter 22). Nothing in this chapter concerns pairs of universes, their creation, or matter and antimatter.

16.26 What we proved, what we computed, what we assumed

PROVED (derived line by line in this chapter; where the Revision record holds the statement, its report and check are named):

- The convergence ratio $(x(h) - x(h/2))/(x(h/2) - x(h/4)) = 4(1 + \frac{15}{16}\frac{d}{c}h^2 + \dots)$ for an error with even powers of h (Section 16.4).
- Richardson extrapolation: $r(h) = (4x(h/2) - x(h))/3 = X - \frac{1}{4}dh^4 + \dots$, $R = (64x(h/4) - 20x(h/2) + x(h))/45 = X + O(h^6)$, and $R - r(h/2) = \frac{1}{64}dh^4 + O(h^6)$, so that the stated U over-estimates the error of R when h is small (Section 16.5).
- The Rust uncertainty $U_{Rust} = \frac{16}{15}|x_c - x_r|$ for a fourth-order method whose step is halved, and in general the factor $2^p/(2^p - 1)$ for order p (Section 16.6, Exercise 3).
- The tolerance rule as a consequence of the triangle inequality, and the propagated uncertainties $U_F = U_E + TU_S$, $U_\Omega = U_F + NU_\mu$, $3(U_{I_3} + U_{I_t})$ for dE/da_4, and the factor 2 for ΔE_x (Section 16.7).
- The exact free levels at zero momentum: 0 and $\pm\sqrt{M^2 + (n\pi/L)^2}$ for even parity, $\pm\sqrt{M^2 + p_l^2}$ with $\tan(p_l L) = -p_l/M$ (one root in each interval) for odd parity, and the zero mode $A\,e^{My}$ with $A = \sqrt{2M/(1 - e^{-2ML})}$ (Section 16.13; `Revision/kohn_sham/reports/ks-theory-python.json`, check bc_exact_k0_spectra).
- The staggered discretisation: second-order centred differences and averages with even-power errors, the symmetric tridiagonal matrix, the rotated frame for odd parity with $m_2 = M\cos 2\phi - K\sin 2\phi$, $k_2 = M\sin 2\phi + K\cos 2\phi$ and the extra term ϕ' (Section 16.14).
- The pivot recursion $q_r = d_r - x - o_{r-1}^2/q_{r-1}$ and, with Sylvester's law, the Sturm count; Gershgorin's bound; the number of bisection steps (Section 16.15).
- The exact discrete zero mode $u_p = q^p u_0$, $q = (1 + Mh/2)/(1 - Mh/2)$, $\ln q = Mh + (Mh)^3/12 + \dots$; the Hellmann-Feynman theorem for symmetric matrices; the brane-band slope $c = e^{-a_{4,0}}\frac{2M}{1-e^{-2ML}}\frac{1-e^{-(2M-H)L}}{2M-H}$ (Section 16.15; same report, check brane_band_slope).
- The slope $dN/d\mu = \frac{1}{T}\sum gf(1-f) > 0$ and the uniqueness of the chemical potential; the two-level estimate $\mu \approx \frac{\varepsilon_0+\varepsilon_1}{2} - \frac{T}{2}\ln\frac{g_1}{g_0}$; Newton's method and its quadratic convergence; the width $3 \cdot 2^{-51}/N'$ of the zero interval of the direct sum near $N = 8$; the exact rewriting $W = -d - H_{th} + P$ of the Mermin residual (Section 16.20).

Quoted, not proved here: Sylvester's law of inertia and the spectral theorem for symmetric matrices (Sections 16.14 and 16.15). The first-order rounding bounds B_{direct} and B_{well} are derived in the Rust solver's documentation (`Revision/kohn_sham/solver/src/mermin.rs`); this chapter derives their main terms.

COMPUTED (numbers from the records named, each reproduced by a notebook of the chapter):

- The reference solver's self-checks: 37 checks, all PASS (`Revision/kohn_sham/reports/ks-reference.json`); among them the exact free levels reproduced to 2.8×10^{-14}, convergence ratios between 3.99977 and 4.00019, the brane-band slope to 2.6×10^{-15}, and the fourth-grid validation with the largest ratio 0.787 (Notebooks 16a and 16b).
- The full cross-check: 31 checks, all PASS, 162691 comparisons, no ratio above 0.495 (the report `Revision/kohn_sham/reports/ks-crosscheck.json` and its table `ks-crosscheck-table.csv` in the same folder). Notebook 16a reproduces, for five states, the reference results

byte for byte, the Rust canonical results exactly, the canonical-minus-refined differences of `Revision/kohn_sham/checker/rust-refinement.json`, 97 table rows, and the worst cases of six classes; all 5140 of its comparisons pass, the largest with the ratio 0.4952.

- The chemical potential: the faulty value 0.2100104489071649 of the first cross-check reproduced in all sixteen digits by bisection on the direct sum; the 40-digit roots 0.21001044973390… (Rust levels) and 0.21001044973430… (reference levels), 4.0×10^{-13} apart; the bounds $B_{direct} = 1.287 \times 10^{-8}$ and $B_{well} = 3.154 \times 10^{-16}$ of N8_lamm1_a00_T10 and of all 45 thermal states with $N = 8$ (`Revision/kohn_sham/reports/ks-rust-mermin-roots.json`; Notebook 16c).

ASSUMED:

- that the grid errors have the assumed forms (even powers of h for the reference, fourth order for the Rust solver), tested by the ratio test on every level and by a fourth grid for one state, not proved for the self-consistent problem;
- that the measured uncertainties bound the errors (the factor 3 of the tolerance rule allows for estimates that are somewhat too small); Section 16.20 shows one way this can fail: a repeated computation that shares a rounding error does not measure it;
- the inputs shared by both programs, listed in Section 16.25: the functional, the Z2 mirror brane, the good sector; CHOSEN: the regular tip and $L = 3$ (the cross-check compares the two programs at this L; the dependence on L is measured separately, Section 16.25); CONVENTION, justification OPEN: the filling of the levels; PRESCRIBED BACKGROUND: the history $a_4 = AHx_4$.

HYPOTHESIS: none is used in this chapter. **OPEN:** the time-dependent (non-adiabatic) problem, the justification of the filling convention, any test that could confirm the shared inputs beyond the study of the tip cutoff L (29 recorded states in `Revision/kohn_sham/tip_convergence/`) and the diagnostics of Section 16.25, which can show where an input fails but cannot confirm it, and the large-L limit wherever that study does not establish it. It establishes the limit (numerically, with uncertainties) only for the states and quantities that its `README.md` marks converged or with a geometric tail, and no limit at all for $N = 688$ at $a_{4,0} = 0$ or for the 7 interacting states whose self-consistent iteration fails before the successive differences of E_{KS} meet its rule for a geometric tail. In 8 further interacting states some quantities other than E_{KS} do not meet the rule (the interaction energy, the integrals of p_3 and p_t, LUMO, the Kohn-Sham gap; `tip-convergence.json`, `analysis.fixed`), and the recorded states and quantities that the study does not compute at $L \neq 3$ are not covered.

16.27 Exercises

Exercise 1 (Richardson by hand). Notebook 16a prints the Kohn-Sham energy of N8_lamm2_a00 on the three grids: $E_{KS}(300) = 0.002862539189$, $E_{KS}(600) = 0.002862623929$, $E_{KS}(1200) = 0.002862645113$. Compute the convergence ratio, the one-step values $r(h)$ and $r(h/2)$, the three-grid value R and its uncertainty U. Compare R with the notebook's 0.0028626521737 and explain the difference.

Answer. The differences are $x(h)-x(h/2)=-8.4740\times10^{-8}$ and $x(h/2)-x(h/4)=-2.1184\times10^{-8}$, and their ratio is 4.0002: second order. Then $r(h)=(4\cdot0.002862623929-0.002862539189)/3=(0.011450495716-0.002862539189)/3=0.008587956527/3=0.0028626521757$, and $r(h/2)=(4\cdot0.002862645113-0.002862623929)/3=(0.011450580452-0.002862623929)/3=0.008587956523/3=0.0028626521743$. So $R=(16\,r(h/2)-r(h))/15=r(h/2)+(r(h/2)-r(h))/15=0.0028626521743-0.0000000000001=0.0028626521742$, and $U=|R-r(h/2)|+2\cdot10^{-12}=0.9\times10^{-13}+2\times10^{-12}=2.1\times10^{-12}$, as in the notebook. Our R differs from the notebook's 0.0028626521737 by about 5×10^{-13}, because the printed grid values are rounded to 10^{-12}: the weights of R are $\frac{64}{45}$, $-\frac{20}{45}$ and $\frac{1}{45}$, so rounding errors of up to 0.5×10^{-12} in the inputs can move R by up to $\frac{64+20+1}{45}\cdot0.5\times10^{-12}=0.94\times10^{-12}$. The notebook computes with the unrounded values. (Useful identity: $R=r(h/2)+(r(h/2)-r(h))/15$, which follows from $16r(h/2)-r(h)=15r(h/2)+(r(h/2)-r(h))$.)

Exercise 2 (the worst comparison). The worst comparison of the whole cross-check is the energy density at the tip of N8_lamm2_a00: Rust gives -10.1822650611886, the reference -10.182265056614, and the tolerance is 9.238×10^{-9} (`Revision/kohn_sham/reports/ks-crosscheck.json`, check emt_brane_tip_values). Compute the difference and the ratio, and the sum $U_{ref}+U_{Rust}$ of the two uncertainties.

Answer. $|x_{Rust}-x_{ref}|=10.1822650611886-10.182265056614=4.5746\times10^{-9}$. The ratio is $4.5746\times10^{-9}/9.238\times10^{-9}=0.495$, the largest ratio of the record. The tolerance is $3(U_{ref}+U_{Rust})+10^{-12}\max(1,10.18)$, so $U_{ref}+U_{Rust}=(9.238\times10^{-9}-1.018\times10^{-11})/3=3.076\times10^{-9}$. The difference is about 1.5 times this sum. Since the difference can exceed the sum of the two UNCERTAINTIES only if at least one error exceeds its uncertainty (Section 16.7: the difference never exceeds the sum of the two errors), at least one of the two estimates is too small at the tip, by a factor of up to about 1.5. The factor 3 of the rule absorbs this, which is why it is there. In the whole cross-check only two classes have a largest ratio above $\frac{1}{3}$, where the factor 3 is needed at all: emt_brane_tip_values and ground_profiles, both with 0.495 at this tip value; the next largest class maximum is 0.324 (ground_eigenvalues; the table of Section 16.8).

Exercise 3 (the factor for a method of order p). A method has the error $x(h)=X+c\,h^p+\ldots$. It is run with the step h (result x_c) and with $h/2$ (result x_r). Show that the error of x_c is $\frac{2^p}{2^p-1}(x_c-x_r)$, and evaluate the factor for $p=2$ and $p=4$. Use it to compute U_{Rust} for E_{KS} of N688_lam0_a00, where Notebook 16a measures $|x_c-x_r|=7.529\times10^{-10}$.

Answer. $x_c=X+e$ with $e=ch^p$, and $x_r=X+c(h/2)^p=X+e/2^p$. Subtracting, $x_c-x_r=e(1-2^{-p})=e\,\frac{2^p-1}{2^p}$, so $e=\frac{2^p}{2^p-1}(x_c-x_r)$. For $p=2$ the factor is $\frac{4}{3}$, for $p=4$ it is $\frac{16}{15}$, the factor of Section 16.6. For N688_lam0_a00: $U_{Rust}=\frac{16}{15}\cdot7.529\times10^{-10}=8.031\times10^{-10}$. (The same algebra gives Richardson's first step: $X=x_r-(x_c-x_r)/(2^p-1)$, which for $p=2$ is $(4x_r-x_c)/3$.)

Exercise 4 (a Sturm count by hand). Take the even-parity matrix of Section 16.14 for $G=2$ cells ($h=1.5$, $M=1$, $j=+1$): the unknowns are u_0,w_1,u_1, and $T=\begin{pmatrix}0&a&0\\a&0&b\\0&b&0\end{pmatrix}$ with $a=\frac{1}{h}+\frac{M}{2}$, $b=-\frac{1}{h}+\frac{M}{2}$. (i) Compute a, b and the three eigenvalues. (ii) Compute the pivots at $x=0.5$ and the Sturm count $c(0.5)$. (iii) Construct the discrete zero mode. (iv) Compare the positive eigenvalue with the exact level 1.447972.

Answer. (i) $a=\frac{2}{3}+\frac{1}{2}=\frac{7}{6}$ and $b=-\frac{2}{3}+\frac{1}{2}=-\frac{1}{6}$. The determinant of $T-\varepsilon\mathbb{1}$, expanded along the first row, is $-\varepsilon(\varepsilon^2-b^2)-a(-a\varepsilon)=-\varepsilon(\varepsilon^2-a^2-b^2)$, so the eigenvalues are 0 and $\pm\sqrt{a^2+b^2}=\pm\sqrt{\frac{49}{36}+\frac{1}{36}}=\pm\sqrt{\frac{50}{36}}=\pm1.178511$. (ii) $q_1=0-0.5=-0.5$; $q_2=0-0.5-a^2/q_1=$

$-0.5+1.361111/0.5 = -0.5+2.722222 = 2.222222$; $q_3 = 0-0.5-b^2/q_2 = -0.5-0.027778/2.222222 = -0.5-0.0125 = -0.5125$. Two pivots are negative, so $c(0.5) = 2$: indeed two eigenvalues, -1.178511 and 0, lie below 0.5. (iii) $q = (1+Mh/2)/(1-Mh/2) = 1.75/0.25 = 7$, so $u_1 = 7u_0$ and $w_1 = 0$. Check the row of w_1: $a\,u_0 + b\,u_1 = \frac{7}{6}u_0 - \frac{1}{6}\cdot 7u_0 = 0$. Normalised with $\sum u^2 h = 1$: $u_0^2(1+49)\cdot 1.5 = 1$, so $u_0 = 0.11547$, $u_1 = 0.80829$. (iv) The coarse grid gives 1.178511 instead of 1.447972, an error of 0.27: with only two cells the h^2 error is large, and Notebook 16b shows how it shrinks by a factor 4 per halving of h.

Exercise 5 (how many halvings). For the even-parity matrix with $G = 300$ cells ($M = 1$, $L = 3$, $k = 0$), find Gershgorin's starting interval and the number of bisection steps needed to locate the zero mode to 10^{-14}.

Answer. $h = 3/300 = 0.01$, so the neighbour entries are $\frac{1}{h} + \frac{1}{2} = 100.5$ and $-\frac{1}{h} + \frac{1}{2} = -99.5$. Every inner row has the radius $100.5 + 99.5 = 200$ and the diagonal is zero, so the interval is $[\min(d-\rho) - 1, \max(d+\rho) + 1] = [-201, 201]$, of width $W = 402$. After n halvings the width is $402/2^n$, and $402/2^n \le 10^{-14}$ needs $2^n \ge 4.02 \times 10^{16}$, that is $n \ge \log_2(4.02 \times 10^{16}) = 55.2$: 56 halvings. (For $G = 150$ the same reasoning gives 55, the number of Notebook 16b; doubling G doubles W and costs one more halving.)

Exercise 6 (the accuracy of the discrete zero mode). For $G = 150$ ($h = 0.02$, $M = 1$), compute $\ln q$ to nine decimals with the series of Section 16.15 and compare with Mh. By how much does the discrete exponential grow faster than e^{My} across the whole interval $L = 3$, and is this consistent with the distance 6.93×10^{-5} that Notebook 16b measures?

Answer. $\ln q = Mh + (Mh)^3/12 + \cdots = 0.02 + 0.000008/12 = 0.02 + 0.000000667 = 0.020000667$ (the next term, $(Mh)^5/80 = 4 \times 10^{-11}$, does not change these digits). So the discrete exponential grows like $e^{1.0000333\,y}$ instead of e^y: over the 150 cells the exponents differ by $150 \cdot 6.67 \times 10^{-7} = 1.0 \times 10^{-4}$. Two effects of order h^2 make up the measured distance, and both raise the discrete values near the brane, where a is largest ($A\,e^{My} = 1.402$ at the last half node $y = -0.01$). (i) The rate. A mode e^{ry} normalised to $\int a^2 dy = 1$ has $a(0)^2 = 2r/(1 - e^{-2rL})$; increasing $r = M$ by the relative amount $(Mh)^2/12 = 3.33 \times 10^{-5}$ raises $\ln a$ near the brane by about $(\frac{1}{2M} - \frac{Le^{-2ML}}{1-e^{-2ML}} + y) \cdot 3.33 \times 10^{-5} = (0.5 - 0.0075 - 0.01) \cdot 3.33 \times 10^{-5} = 1.61 \times 10^{-5}$, that is by $1.61 \times 10^{-5} \cdot 1.402 = 2.3 \times 10^{-5}$ in absolute size. (ii) The normalisation. The notebook normalises with the midpoint sum $\sum u^2 h$, not with the integral. Over one cell centred at y_p the integral of e^{2My} is $e^{2My_p}(e^{Mh} - e^{-Mh})/(2M) = h\,e^{2My_p}\,\frac{\sinh(Mh)}{Mh} = h\,e^{2My_p}(1 + \frac{(Mh)^2}{6} + \dots)$, so the sum is smaller than the integral by the relative amount $(Mh)^2/6 = 6.7 \times 10^{-5}$; dividing by the square root of a number that is too small by this amount raises the normalised values by half of it, 3.3×10^{-5}, which is 4.7×10^{-5} at the value 1.402. Together: $2.3 \times 10^{-5} + 4.7 \times 10^{-5} = 7.0 \times 10^{-5}$, consistent with the measured 6.93×10^{-5}. (To test the split yourself, compute the half nodes `y = -L + (np.arange(G) + 0.5) * h` at the start of the function `zero_mode` of Notebook 16b and change the function in two ways. First, with `u = np.exp(M * y)`, the values e^{My} with the exact rate M, and the normalisation by the sum kept, only part (ii) remains: the distance printed by the notebook drops to about 4.7×10^{-5}. Second, with `r = log_q / h` and `u = np.exp(r * y)`, the values e^{ry} with $r = \ln q/h$, divided by `math.sqrt((1 - math.exp(-2 * r * L)) / (2 * r))`, the square root of the exact integral of e^{2ry} from $-L$ to 0, in place of the sum, only part (i) remains: about 2.3×10^{-5}. The values $u_p = q^p$ of the notebook are $e^{r(y_p+L-h/2)}$, larger than e^{ry_p} by a constant factor, so they must be replaced by e^{ry} before the exact integral is used.) Both are of order h^2: $(Mh)^2/12$ and $(Mh)^2/6$.

Exercise 7 (the chemical potential of N8_lamm1_a00_T10 by hand). With the levels $\varepsilon_0 = 0.000245562708$ ($g_0 = 8$), $\varepsilon_1 = 0.430761462627$ ($g_1 = 24$), $\varepsilon_2 = 0.587973061749$ ($g_2 = 48$) and

$T = 0.01$: (i) evaluate the two-level estimate of Section 16.20; (ii) show that the thermal particles of the level ε_2 lower μ by about $\frac{T}{2}P_2/P_1$ and evaluate the correction; (iii) compare with the 40-digit root 0.2100104497339.

Answer. (i) $\mu_0 = \frac{0.000245562708+0.430761462627}{2} - 0.005\ln 3 = 0.215503512668 - 0.005493061443 = 0.210010451225$. (ii) The Mermin condition $H_{th} = P_1 + P_2$ reads $g_0 e^{-(\mu-\varepsilon_0)/T} = g_1 e^{-(\varepsilon_1-\mu)/T}(1 + P_2/P_1)$. Taking logarithms as in Section 16.20 gives $\mu = \mu_0 - \frac{T}{2}\ln(1 + P_2/P_1) \approx \mu_0 - \frac{T}{2}\,\frac{P_2}{P_1}$, because $\ln(1 + s) \approx s$ for small s. With $\mu \approx 0.2100104$: $P_2 = 48\,e^{-(0.587973-0.210010)/0.01} = 48\,e^{-37.796} = 48{\cdot}3.85{\times}10^{-17} = 1.85{\times}10^{-15}$ and $P_1 = H_{th} = 6.21{\times}10^{-9}$, so $P_2/P_1 = 2.97{\times}10^{-7}$ and the correction is $0.005 \cdot 2.97 \times 10^{-7} = 1.49 \times 10^{-9}$. (iii) $\mu \approx 0.210010451225 - 0.000000001488 = 0.210010449737$, within about 3×10^{-12} of the 40-digit root 0.2100104497339 (the remaining difference comes from the approximations $1/(1 + e^s) \approx e^{-s}$ and $\ln(1 + s) \approx s$, and from rounding the levels to twelve decimals). The direct sum in doubles can hardly see the level ε_2: its particles, 1.8×10^{-15}, are one or two spacings of the doubles near 8, so the direct sum blurs an effect that moves μ by 1.5×10^{-9}, the size of the error of the first cross-check.

Exercise 8 (another activated state). For the state N8_lam0_a00_T10 the record gives $n = 5$ levels and $dN/d\mu = 1.229 \times 10^{-6}$ (`Revision/kohn_sham/reports/ks-rust-mermin-roots.json`). Estimate the width of the interval of μ on which the direct residual is exactly zero, and the main term of B_{direct}. Compare with the error of the direct sum for this state printed by Notebook 16c ($+2.72 \times 10^{-10}$).

Answer. The width is $3 \cdot 2^{-51}/N' = 1.332 \times 10^{-15}/1.229 \times 10^{-6} = 1.08 \times 10^{-9}$, as for N8_lamm1_a00_T10, because N' is almost the same. The main term of the bound is $(n + 2)\,\epsilon_{mach} N/N' = 7 \cdot 2.220 \times 10^{-16} \cdot 8/1.229 \times 10^{-6} = 1.012 \times 10^{-8}$, the record's 1.012×10^{-8} (the other terms are about 10^{-16}). The actual error, 2.72×10^{-10}, lies inside the zero interval's width and far inside the bound. Its sign is positive here: where the zero interval lies relative to the root depends on how the individual terms of the sum are rounded, so bisection can stop above or below the root. A bound tells how large an error can be; it does not tell its sign.

17 The a4 equations with the Kohn-Sham source: a prescribed background

Chapters 14 to 16 computed the Kohn-Sham states of the field dirac16complex in the author's primordial universe, at five instants of the history $a_4 = Hx_4$ along which 3-space inflates and the three extra times deflate exponentially. Chapter 12 derived the field equations that gravity imposes on the function $a_4(x_4)$. This chapter puts the two together. It asks one question: if the energy and momentum of the Kohn-Sham gas are put on the right-hand side of the field equations of gravity, is the history $a_4 = Hx_4$ a solution? The answer is no, and the chapter proves exactly why. Two complete notebooks repeat every step: Notebook 17a tests the three conditions that the field equations impose on every source against all 75 recorded Kohn-Sham ground states, and Notebook 17b shows that the failure is forced by the conservation of energy and momentum itself.

17.1 What this chapter does, and why

The question. In Einstein's theory, and in its generalisation used in this book, matter and geometry are tied together: the curvature of the metric equals a constant times the energy and momentum of the matter. In Chapters 14 and 15 we did something weaker. We took the author's metric with the history $a_4 = Hx_4$ as GIVEN, and we computed how a gas of dirac16complex quanta settles into its lowest state at five instants of that history. We never asked whether the gas, through its own energy and momentum, would make the metric that it moves in. This chapter asks that question.

Why it matters. If the answer were yes, the history $a_4 = Hx_4$, with the gas in it, would be a solution of the coupled equations of gravity and matter: a possible universe of this theory. Every energy, pressure and equation of state computed along it would then be a prediction of the theory. If the answer is no, the history is a **prescribed background**: a stage that we chose, on which the gas moves as a **test field** whose own gravity is ignored. Its energies and pressures are still well-defined numbers, but they describe a gas in a chosen geometry, not a self-consistent universe. The Revision record states the answer in `Revision/field_equations_a4/reports/ks-source-conditions.json`: no recorded Kohn-Sham state is an admissible source (the record tests the 75 ground states, the only states whose profiles it stores), and the history is a prescribed background without back-reaction. This chapter derives that statement from the beginning and checks every number of it.

What is derived, in order.

- The field equations of a_4 and the most general source they allow (Section 17.3).
- The three **source conditions**: no dependence on the hidden coordinate x_0 (C1, Section 17.4), the algebraic condition $p_3 + p_t = 2p_0$ (C2, Section 17.5), and, for the linear history $a_4 = AHx_4 + a_0$, equal pressures and a constant energy density (C3, Section 17.6). They are derived on the background $b_4 = 1$ of the author's metric of 2026-10-14, on which the Kohn-Sham states are computed; the record states that the verdict holds for every second function $b_4(x_4)$: C1 holds unchanged, so the x_0-dependent Kohn-Sham profiles are not an admissible source for any b_4 (`Revision/field_equations_a4/reports/ks-source-conditions.json`, check `ks_verdict_holds_for_every_b4`; Section 12.12 gives the field equations with b_4).
- What the 75 recorded Kohn-Sham ground states are and which numbers of them we use (Section 17.7); then Notebook 17a, which evaluates C1, C2 and C3 on all of them (Sections 17.8 to 17.11).
- Why the states fail: every source of the field equations must be conserved, and what the Kohn-Sham states conserve (Section 17.12); the conservation law in the hidden coordinate y (Section 17.13); for a conserved source C2 says exactly that the hidden pressure p_0 is flat (Section 17.14); the integrated form and the averaged ratio (Section 17.15); the energy exchange along the history and the propagation of the constraint, which turn C3 into $p_3 = p_t$ (Section 17.16).
- The field equations averaged over the hidden direction: the moment equations, which of them can hold together, their first integral, and what can and cannot be integrated with the Kohn-Sham source, within a stated approximation (Section 17.17); then Notebook 17b (Sections 17.18 to 17.21).

- What "prescribed background" means, and what remains open (Section 17.22); the summary of statuses (Section 17.23); exercises with complete answers (Section 17.24).

The two notebooks.

notebook	what it computes	PASS lines	figures
17a	the three source conditions derived from the record, evaluated on the 75 recorded Kohn-Sham ground states	16	7
17b	the conservation law in the author's metric; why a conserved source fails C2 and C3; the averaged equations and their first integral	20	6

Neither needs Rust: both read the stored results of the Revision Rust solver and the Revision reports, and compute everything else with numpy and sympy.

The status of every statement. As everywhere in this book, every statement carries one of five labels: PROVED (exact, with the verifier file and check name), COMPUTED (numerical, with its measured error), ASSUMED, HYPOTHESIS, OPEN. In this chapter:

- PROVED: the three source conditions (Sections 17.4 to 17.6), the conservation law and its consequences (Sections 17.12 to 17.16), the moment equations and their first integral (Section 17.17), and the absence of a solution without matter in Einstein gravity.
- COMPUTED: every statement about the 75 recorded ground states (Notebooks 17a and 17b), each with the record file it reproduces.
- ASSUMED: the history $a_4 = Hx_4$ on which the Kohn-Sham states were computed (it is the prescribed background); the good sector, the Z2 mirror at the brane and the tip cutoff of the Kohn-Sham model (Chapter 14); in Section 17.17, the approximation that keeps only two of the averaged field equations (it is stated there with its error).
- OPEN: what metric the Kohn-Sham gas would produce with back-reaction, and whether any state of dirac16complex is an admissible source of the author's metric (Section 17.22).
- HYPOTHESIS: none in this chapter.

Honesty about what this chapter is not. Nothing in this chapter concerns the creation of universes, pairs of universes, or matter and antimatter. In particular the sign changes that appear in it (a pressure that changes sign along the hidden direction, the states with couplings $+\lambda$ and $-\lambda$ in figure 4 of Notebook 17b) are properties of particular recorded states; they are not the pairing theorems of Chapters 18 to 20.

17.2 The words and symbols of this chapter

Each word is defined in plain terms here; the later sections make each definition precise with formulas.

- **Coordinates** $x_0, \ldots, x_7$, in the author's order: x_1, x_2, x_3 are ordinary 3-space, which inflates; x_4 is the time; x_5, x_6, x_7 are the three **extra times**, which behave like time and **deflate exponentially**; x_0 is the hidden space direction. The angle $z = 6Hx_0$ runs from 0 to $\pi/2$; $H > 0$ is a constant of the author's metric, with the unit of an inverse length.

- **Prime**: on a_4 it means the derivative with respect to the time, $a_4' = da_4/dx_4$, $a_4'' = d^2a_4/dx_4^2$; the code writes them `ad1` and `ad2`. On a function of the hidden coordinate it means d/dy; we always say which.

- **Hidden coordinate** $y = \ln(\sin z)/(6H)$: a second way to number the points of the hidden direction, used by the Kohn-Sham computations. It grows when x_0 grows. $y = 0$ is the end $z = \pi/2$, called the **brane**; $y \to -\infty$ is the end $z \to 0$, called the **tip**. The Kohn-Sham computations stop at $y = -L = -3$, the **tip cutoff**; the region $-3 \le y \le 0$ is the **patch**.

- **Metric**, **scale factor**: the table $g_{\mu\nu}$ that turns coordinate steps into squared lengths, and the number $\sqrt{|g_{\mu\mu}|}$ by which a step along one direction must be multiplied to give a length.

- **Field equations of gravity**: $\sum_{k=1}^{3} \alpha_k E_{(k)}{}^{\mu}{}_{\nu} + \Lambda\, \delta^{\mu}_{\nu} = \kappa\, T^{\mu}{}_{\nu}$. On the left are the three **Lovelock tensors** $E_{(1)}$ (the Einstein tensor), $E_{(2)}$ (the Gauss-Bonnet tensor) and $E_{(3)}$, built from the curvature of the metric, weighted by the **couplings** $\alpha_1, \alpha_2, \alpha_3$, and the **cosmological constant** Λ. $\kappa > 0$ measures the strength of gravity. **Einstein gravity** is $\alpha_1 = 1$, $\alpha_2 = \alpha_3 = 0$. The symbol δ^{μ}_{ν} is 1 when $\mu = \nu$ and 0 otherwise.

- **Energy-momentum tensor** $T^{\mu}{}_{\nu}$, also called the **source**: an 8×8 table at every point that says how much energy and momentum the matter has and how they flow. Its diagonal parts are the **energy density** $\rho = -T^{x_4}{}_{x_4}$ and the **pressures** p_3 (each direction of 3-space), p_t (each extra time) and p_0 (the hidden direction); its possible **mixed** parts are $q_{40} = T^{x_4}{}_{x_0}$ and $q_{04} = T^{x_0}{}_{x_4}$.

- **Admissible source**: a source for which the field equations of the author's metric can hold. **Source conditions** C1, C2, C3: the three conditions that an admissible source must meet (Sections 17.4 to 17.6).

- **Linear member**: the history $a_4 = AHx_4 + a_0$ with constants A (the **slope**) and a_0. For $A > 0$ the extra-time scale factor e^{-a_4} shrinks exponentially. The history of the Kohn-Sham computations is $A = 1$, $a_0 = 0$.

- **Slice**: one instant of the history, labelled by the value $a_{4,0}$ of a_4 there; the Kohn-Sham states were computed at the five slices $a_{4,0} = 0, 0.5, 1, 1.5, 2$.

- **Kohn-Sham state**: a many-quantum state of dirac16complex computed with the Kohn-Sham method (Chapters 13 to 15). A recorded state is named like `N136_lamm2_a20`: particle number $N = 136$, coupling $\lambda = -\lambda_2$ (`lamm2`; `lamm1` is $-\lambda_1$, `lam0` is $\lambda = 0$, `lamp1` is $+\lambda_1$, `lamp2` is $+\lambda_2$), slice $a_{4,0} = 2.0$ (`a20`).

- Words of the Kohn-Sham method used again here (Chapters 13 to 15 define them in full): an **orbital** is the wave of one quantum, and an **eigen-orbital** one that solves the Kohn-Sham equation with a definite energy; the **Fermi level** is the energy that separates the occupied orbitals from the empty ones; a state is **self-consistent** when the potentials computed from its own density are the potentials its orbitals were computed with; the **good sector** is the set of orbitals that do not depend on the extra times x_5, x_6, x_7; the **Z2 mirror** is the ASSUMED rule that the hidden direction continues beyond the brane as a mirror image of the computed patch, with the field there fixed by the field on the computed side (Chapter 14 states the rule; record `Revision/kohn_sham/ks-theory.json`, key `boundaryConditions.brane`).

- More words of the Kohn-Sham computations: a **shell** is a group of orbitals with the same energy, and a **closed shell** is a particle number N that fills every orbital up to some energy completely and none above it (so the ground state is unique); the **first-order mean-field potential** is the potential that one quantum feels from the others when the interaction is counted once, to first order in the coupling λ, with the density of the free gas; **fixed occupations** means that the same orbitals stay filled when a_4 is changed a little, even if their energies move.

- **Least squares**: the straight line through a set of points that makes the sum of the squared vertical distances of the points from the line as small as possible.

- **Moment** of a field equation: the equation multiplied by the volume weight e^{6Hy} and integrated over the patch; it involves the source only through its weighted means $\bar{\rho}$, $\bar{p}_3$, $\bar{p}_t$, $\bar{p}_0$. **First integral**: an equation with only first derivatives that every solution of a second-order equation obeys. **Cubic Hermite interpolation**: between two tabulated points, the cubic polynomial with the given values and the given slopes at both ends. **Turning point**: the value of a_4 where a_4' reaches 0. **Branch point**: a value of a_4' where $F(a_4') = 0$, so that the evolution equation cannot be solved for a_4''.

- **Profile**: a component of the source as a function of y, stored at 151 points. **Proper density**: an amount per unit of proper volume, the volume that rulers measure.

- **max|T|**: the largest absolute value of ρ, p_3, p_t and p_0 of a state over the whole patch. We divide by it to compare states of very different size.

- **Integral over the patch** $\int X$: the total amount of a density X in the computed region, $2\,\mathrm{Vol}_7 \int_{-3}^{0} e^{6Hy} X \, dy$ (Section 17.7). **Weighted mean** $\bar{X}$: the integral divided by the proper volume of the patch.

- **Covariant divergence** $\nabla_\mu T^\mu{}_\nu$: the curved-space form of "the change of a quantity in time plus its outflow through the walls of a small box". **Conservation**: zero covariant divergence. **Christoffel symbols** $\Gamma^\lambda{}_{\mu\nu}$: combinations of first derivatives of the metric that say how the coordinate directions turn and stretch from point to point. **Bianchi identity**: the left-hand side of the field equations has zero covariant divergence for every metric.

- **Constraint**: the x_4 component of the field equations (it contains a_4' but no a_4''). **Evolution equation**: the 3-space component minus the extra-time component, $a_4'' F(a_4') = \kappa(p_3 - p_t)$.

- **Prescribed background**: a metric that is chosen, not solved for. **Test field**: matter that moves in a prescribed background while its own gravity is ignored. **Back-reaction**: the effect of the matter's own gravity on the metric; a test field has none.

- **Finite difference**: an estimate of a derivative from neighbouring values in a table. Its **order of accuracy** p: its error falls like h^p when the step h shrinks. **Simpson's rule**: an estimate of an integral from equally spaced values, of order 4.
- **Heat map**: a table drawn as coloured squares, one colour per value. **Symmetric logarithmic axis**: an axis that is logarithmic for large positive and large negative values and linear in a narrow band around zero, so that both signs and many orders of magnitude can be shown.
- **sha256 fingerprint**: a 64-digit code computed from the bytes of a file; two files with the same fingerprint are, for all practical purposes, identical.
- **Units**: as in the Revision runs, $H = 1$ and the fermion mass $m = 1$. Lengths are in units of $1/H$; energy densities and pressures (energy per unit of 7-dimensional volume) in units of m^8; integrals over the patch (energies) in units of m.

17.3 The field equations of a4 and their source

The metric. The author's metric is diagonal; in the order $x_0, \dots, x_7$ its entries are

$$g = \mathrm{diag}(e^{2a_4}\sin^{1/3} z,\ e^{2a_4}\sin^{1/3} z,\ e^{2a_4}\sin^{1/3} z,\ -1,\\ -e^{-2a_4}\sin^{1/3} z,\ -e^{-2a_4}\sin^{1/3} z,\ -e^{-2a_4}\sin^{1/3} z,\ \cot^2 z),$$

with $z = 6Hx_0$ and one free function $a_4(x_4)$. The 3-space scale factor is $e^{a_4}\sin^{1/6} z$ and the extra-time scale factor $e^{-a_4}\sin^{1/6} z$: when a_4 grows, 3-space inflates and the extra times deflate.

The source. Chapter 12 allowed the most general source that the symmetry of the metric suggests:

$$T^{\mu}{}_{\nu} = \mathrm{diag}(p_3, p_3, p_3, -\rho, p_t, p_t, p_t, p_0) + q_{40}\ (\mu = x_4, \nu = x_0) + q_{04}\ (\mu = x_0, \nu = x_4),$$

where every one of $\rho, p_3, p_t, p_0, q_{40}, q_{04}$ may a priori depend on x_4 and on x_0.

The left-hand sides. The Revision record `Revision/field_equations_a4/a4-equations.json` (key `lovelockTensors`) stores every component of the three Lovelock tensors of the author's metric. Writing $a' = a_4'$ and $a'' = a_4''$ for short, the components we need are:

$$E_{(1)}{}^{x_1}{}_{x_1} = 15H^2 - 3a'^2 + a'', \qquad E_{(1)}{}^{x_5}{}_{x_5} = 15H^2 - 3a'^2 - a'',$$
$$E_{(1)}{}^{x_0}{}_{x_0} = 15H^2 - 3a'^2, \qquad E_{(1)}{}^{x_4}{}_{x_4} = 3a'^2 + 21H^2,$$

$$E_{(2)}{}^{x_1}{}_{x_1} = 12a'^4 + 168a'^2H^2 - 180H^4 + a''(-24a'^2 - 40H^2),$$
$$E_{(2)}{}^{x_5}{}_{x_5} = 12a'^4 + 168a'^2H^2 - 180H^4 - a''(-24a'^2 - 40H^2),$$
$$E_{(2)}{}^{x_0}{}_{x_0} = 12a'^4 + 168a'^2H^2 - 180H^4,$$
$$E_{(2)}{}^{x_4}{}_{x_4} = -36a'^4 - 120a'^2H^2 - 420H^4,$$

$$
\begin{aligned}
{E_{(3)}}^{x_1}{}_{x_1} &= -72a'^6 - 648a'^4H^2 - 1944a'^2H^4 + 360H^6 \\
&\quad + a''(360a'^4 + 432a'^2H^2 + 360H^4), \\
{E_{(3)}}^{x_5}{}_{x_5} &= -72a'^6 - 648a'^4H^2 - 1944a'^2H^4 + 360H^6 \\
&\quad - a''(360a'^4 + 432a'^2H^2 + 360H^4), \\
{E_{(3)}}^{x_0}{}_{x_0} &= -72a'^6 - 648a'^4H^2 - 1944a'^2H^4 + 360H^6, \\
{E_{(3)}}^{x_4}{}_{x_4} &= 360a'^6 + 648a'^4H^2 + 1080a'^2H^4 + 2520H^6.
\end{aligned}
$$

We have only regrouped the record's terms: in each x_1x_1 and x_5x_5 component we collected the terms that contain a'' (Exercise 1 asks you to check this against the record's formulas term by term). The components x_2x_2 and x_3x_3 equal x_1x_1, the components x_6x_6 and x_7x_7 equal x_5x_5, and every off-diagonal component, x_4x_0 included, is zero (record: `allOtherComponents`; PROVED, Wolfram report `Revision/field_equations_a4/reports/wolfram-a4-report.json`, check `independent_components`; sympy report `Revision/field_equations_a4/reports/python-a4-report.json`, check `other_components_vanish`).

A pattern. Look at the three blocks. For every order k there are two polynomials, P_k in a' and H and Q_k in a' and H, such that

$$
{E_{(k)}}^{x_1}{}_{x_1} = P_k + a''Q_k, \qquad {E_{(k)}}^{x_5}{}_{x_5} = P_k - a''Q_k, \qquad {E_{(k)}}^{x_0}{}_{x_0} = P_k,
$$

namely $P_1 = 15H^2 - 3a'^2$, $Q_1 = 1$; $P_2 = 12a'^4 + 168a'^2H^2 - 180H^4$, $Q_2 = -24a'^2 - 40H^2$; $P_3 = -72a'^6 - 648a'^4H^2 - 1944a'^2H^4 + 360H^6$, $Q_3 = 360a'^4 + 432a'^2H^2 + 360H^4$. We write the weighted sums as

$$
e_{hh} = \sum_{k=1}^{3} \alpha_k {E_{(k)}}^{h}{}_{h} \text{ (no sum over } h), \qquad \mathcal{P} = \sum_{k=1}^{3} \alpha_k P_k, \qquad \mathcal{Q} = \sum_{k=1}^{3} \alpha_k Q_k,
$$

so that $e_{11} = \mathcal{P} + a''\mathcal{Q}$, $e_{55} = \mathcal{P} - a''\mathcal{Q}$ and $e_{00} = \mathcal{P}$.

The equations. With these abbreviations the 64 field equations reduce to four diagonal equations and two mixed ones:

$$
\begin{aligned}
&\text{constraint } (x_4): && e_{44} + \Lambda = -\kappa\rho, \\
&\text{3-space } (x_1 = x_2 = x_3): && \mathcal{P} + a''\mathcal{Q} + \Lambda = \kappa p_3, \\
&\text{extra times } (x_5 = x_6 = x_7): && \mathcal{P} - a''\mathcal{Q} + \Lambda = \kappa p_t, \\
&\text{hidden } (x_0): && \mathcal{P} + \Lambda = \kappa p_0, \\
&\text{mixed } (x_4x_0 \text{ and } x_0x_4): && 0 = \kappa q_{40}, \quad 0 = \kappa q_{04}.
\end{aligned}
$$

The minus sign in the constraint comes from $T^{x_4}{}_{x_4} = -\rho$. Subtracting the extra-time equation from the 3-space equation gives the **evolution equation**:

$$
(\mathcal{P} + a''\mathcal{Q} + \Lambda) - (\mathcal{P} - a''\mathcal{Q} + \Lambda) = \kappa p_3 - \kappa p_t
$$

(rule: subtract the two equations side by side)

$$2a''\mathcal{Q} = \kappa(p_3 - p_t), \qquad \text{that is} \qquad a_4'' F(a_4') = \kappa(p_3 - p_t), \quad F = 2\mathcal{Q}$$

(rule: $\mathcal{P}$ and Λ cancel; $a''\mathcal{Q} - (-a''\mathcal{Q}) = 2a''\mathcal{Q}$). Written out, $F = 2\alpha_1 - \alpha_2(48a'^2 + 80H^2) + \alpha_3(720a'^4 + 864a'^2H^2 + 720H^4)$, the record's `evolution_F` (PROVED: checks `evolution_factorises` of the sympy report and `evolution_factorises_a4pp_times_F` of the Wolfram report). In Einstein gravity $F = 2$ and the evolution equation is $2a_4'' = \kappa(p_3 - p_t)$.

17.4 Condition C1: a source must not depend on x0

The argument. Read the left-hand side of each equation of Section 17.3. It is built from $a_4'(x_4)$, $a_4''(x_4)$, the constant H and the constants α_k and Λ; it contains no x_0, not even through $\cot z$ or $\sin z$. (The metric itself depends on x_0 through z; these components of the Lovelock tensors, with one index up and one down, do not. PROVED: Wolfram report, checks `P1_structure`, `P2_structure`, `P3_structure`, which state that each tensor $P_{(k)}$ is diagonal and free of x_0; the record defines $E_{(k)} = -P_{(k)}/2^{k+1}$, a constant multiple, so the same holds for $E_{(k)}$ (record `a4-equations.json`, key `conventions.lovelock`); reproduced in Notebook 17a, In [4].) Now take the hidden equation at two points with the same time x_4 and two different hidden coordinates x_0 and $\tilde{x}_0$:

$$\kappa\, p_0(x_4, x_0) = \mathcal{P}(x_4) + \Lambda = \kappa\, p_0(x_4, \tilde{x}_0)$$

(rule: the hidden equation at both points; its left-hand side is the same number at both, because it does not depend on x_0)

$$p_0(x_4, x_0) = p_0(x_4, \tilde{x}_0)$$

(rule: divide by κ, which is not zero). The same three lines with the constraint, the 3-space and the extra-time equations give the same for ρ, p_3 and p_t. The mixed equations say $q_{40} = q_{04} = 0$ outright. So:

C1. Every component of an admissible source is independent of x_0, and the mixed components q_{40} and q_{04} vanish. (PROVED; record `Revision/field_equations_a4/a4-equations.json`, key `generalSource.x0_dependence`.)

The same in the coordinate y. The Kohn-Sham states are stored as functions of $y = \ln(\sin z)/(6H)$. By the chain rule

$$\frac{dy}{dx_0} = \frac{1}{6H} \cdot \frac{\cos z}{\sin z} \cdot 6H = \cot z,$$

(rule: the chain rule; the derivative of $\ln u$ is $1/u$ times the derivative of u, the derivative of $\sin z$ is $\cos z$, and $dz/dx_0 = 6H$) and $\cot z > 0$ for $0 < z < \pi/2$. So y grows strictly with x_0: every value of y belongs to exactly one value of x_0. A function that takes different values at two values of y takes different values at the two corresponding values of x_0. "Depends on y" and "depends on x_0" are the same statement.

How the record measures it. For a state with a nonzero source the record computes the **spread** of the energy density,

$$\frac{\max_y \rho - \min_y \rho}{\max |T|},$$

which is 0 exactly when ρ does not depend on y. C1 needs 0; the record calls a state dependent on x_0 when the spread exceeds its tolerance 10^{-6}.

17.5 Condition C2: the algebraic condition

The derivation. Add the 3-space and the extra-time equations and subtract twice the hidden equation:

$$(\mathcal{P} + a''\mathcal{Q} + \Lambda) + (\mathcal{P} - a''\mathcal{Q} + \Lambda) - 2(\mathcal{P} + \Lambda) = \kappa p_3 + \kappa p_t - 2\kappa p_0$$

(rule: add and subtract the equations side by side; the same operation on both sides keeps an equation true)

$$(\mathcal{P} + \mathcal{P} - 2\mathcal{P}) + (a''\mathcal{Q} - a''\mathcal{Q}) + (\Lambda + \Lambda - 2\Lambda) = \kappa(p_3 + p_t - 2p_0)$$

(rule: collect equal kinds of terms on the left; take out the common factor κ on the right)

$$0 = \kappa(p_3 + p_t - 2p_0)$$

(rule: each bracket on the left is zero). Divided by $\kappa \neq 0$:

C2. Every admissible source has $p_3 + p_t = 2p_0$ at every point and every time. (PROVED; Wolfram report, check `algebraic_identity_x1_plus_x5_minus_2x0`; sympy report, check `algebraic_identity`; reproduced in Notebook 17a, In [4].)

Remarks. C2 holds for every choice of the couplings α_k, of Λ and of the history a_4: it is a condition on the matter alone. It does not involve the energy density. For Einstein gravity the identity behind it is a two-line computation: $(15H^2 - 3a'^2 + a'') + (15H^2 - 3a'^2 - a'') - 2(15H^2 - 3a'^2) = 30H^2 - 6a'^2 - 30H^2 + 6a'^2 = 0$. We call

$$V = p_3 + p_t - 2p_0$$

the **violation** of C2. The record measures its size by $\max_y |V| / \max |T|$ and, for a source averaged over the hidden direction, by the ratio $R = (\int p_3 + \int p_t)/(2 \int p_0)$, which an averaged source satisfying C2 would have equal to 1.

17.6 Condition C3: what the linear member demands

The linear member. For $a_4 = AHx_4 + a_0$:

$$a_4' = AH, \qquad a_4'' = 0$$

(rule: the derivative of $AHx_4 + a_0$ is the constant AH, and the derivative of a constant is 0).

The pressures are equal. The evolution equation of Section 17.3 becomes

$$0 \cdot F(AH) = \kappa(p_3 - p_t) \quad \Longrightarrow \quad p_3 = p_t$$

(rule: insert $a_4'' = 0$; zero times any number is zero; divide by κ). With C2:

$$p_3 + p_3 = 2p_0 \quad \Longrightarrow \quad p_0 = p_3$$

(rule: insert $p_t = p_3$ into $p_3 + p_t = 2p_0$ and divide by 2). So $p_3 = p_t = p_0$; we call the common value p.

The energy density and the pressure are constant. In the constraint, $e_{44} = \sum_k \alpha_k {E_{(k)}}^{x_4}{}_{x_4}$ contains only a' and H (Section 17.3), and $a' = AH$ is a constant. So $-\kappa\rho = e_{44}(AH) + \Lambda$ is the same number at every time. In the same way the hidden equation gives $\kappa p = \mathcal{P}(AH) + \Lambda$, the same number at every time.

C3. Along the linear member $a_4 = AHx_4 + a_0$ an admissible source has $p_3 = p_t = p_0$, and ρ and these pressures do not change with x_4. (PROVED; sympy and Wolfram reports, check `linear_member_equal_pressures`; reproduced in Notebook 17a, In [4].) In Einstein gravity the record gives the values: $\kappa\rho = -(21 + 3A^2)H^2 - \Lambda$ and $\kappa p = (15 - 3A^2)H^2 + \Lambda$ (record `a4-equations.json`, keys `linearMember.rhoEinstein` and `linearMember.pEinstein`). For the history of the Kohn-Sham computations, $A = 1$, this is $\kappa\rho = -24H^2 - \Lambda$ and $\kappa p = 12H^2 + \Lambda$.

What C3 asks of a gas. A gas on the linear history must keep its energy density constant while 3-space inflates and the extra times deflate, and it must push equally hard along 3-space, along the extra times and along the hidden direction, at every instant. Section 17.16 shows that the first demand follows from the second: once the pressures p_3 and p_t are equal, conservation keeps ρ constant.

No source at all. Could the empty source $T = 0$ be admissible? In Einstein gravity the constraint and the hidden equation read $3a'^2 + 21H^2 + \Lambda = -\kappa\rho$ and $15H^2 - 3a'^2 + \Lambda = \kappa p_0$. With $\rho = p_0 = 0$:

$$(3a'^2 + 21H^2 + \Lambda) - (15H^2 - 3a'^2 + \Lambda) = 0 - 0$$

(rule: subtract the second equation from the first, with $\rho = p_0 = 0$ on the right)

$$6a'^2 + 6H^2 = 0$$

(rule: $\Lambda - \Lambda = 0$, $3a'^2 + 3a'^2 = 6a'^2$, $21H^2 - 15H^2 = 6H^2$). A square of a real number is never negative, and $6H^2 > 0$ for $H > 0$, so the left side is positive: there is no solution. (PROVED; Wolfram report, check `einstein_no_vacuum_solution`; reproduced in Notebook 17a, In [19].) The author's metric always needs matter.

17.7 The recorded Kohn-Sham states as a candidate source

What was computed. The Revision Rust solver (Chapter 15) computed, at each slice $a_{4,0}$ of the history $a_4 = Hx_4$, the self-consistent Kohn-Sham ground state of N quanta of dirac16complex in the author's metric with a_4 held at its slice value $a_{4,0}$ (the stationary-slice, adiabatic ansatz of Chapter 14; between the slices the extra times keep deflating). It used the good sector (no dependence on the extra times), the Z2 mirror at the brane and the tip cutoff at $y = -3$, all ASSUMED (Chapter 14). The recorded states are all combinations of

- three particle numbers: $N = 8$ (the eight brane zero modes, the levels of zero 3-momentum and zero energy) and the closed shells $N = 136$ and $N = 688$ (record `Revision/kohn_sham/results/parameters.json`, key `particleNumbers`);
- five couplings: $\lambda = 0$, $\pm\lambda_1$ and $\pm\lambda_2$, chosen for each N so that the largest first-order mean-field potential along the whole history is about $0.1\,m$ and $0.3\,m$ (the same file, key `couplingCalibration`; λ is rounded to four significant digits, so the recorded potentials lie very slightly off these values, in either direction: for $N = 8$, $\lambda_1 = 0.01946$ and $\lambda_2 = 0.05838$ give $0.1000011\,m$ and $0.3000034\,m$ (above), for $N = 136$, $\lambda_1 = 0.0009298$ and $\lambda_2 = 0.002789$ give $0.0999984\,m$ and $0.2999522\,m$ (below), and for $N = 688$, $\lambda_1 = 0.0001846$ and $\lambda_2 = 0.0005538$ give $0.1000001\,m$ and $0.3000004\,m$, again above);
- five slices: $a_{4,0} = 0, 0.5, 1, 1.5, 2$.

That makes $3 \times 5 \times 5 = 75$ states. They are the ground states, at zero temperature, of the canonical matrix of Chapter 15. That matrix also holds 135 thermal states, at the three temperatures 0.01, 0.02 and 0.05 (Chapter 15); the record stores no profiles for them (the folder `Revision/kohn_sham/results/thermo` holds only the table `thermodynamics.csv`), so they are not tested in this chapter (Section 17.17). In this chapter "the recorded states" are the 75 ground states.

What is stored for each state. A **profile** file `Revision/kohn_sham/results/ground/profiles/<name>.csv` with the proper densities at the 151 points $y = -3, -2.98, \ldots, 0$ (step 0.02), among them the four columns `rho`, `p3`, `p_t`, `p0`; and a row of the table `Revision/kohn_sham/results/ground/emt-integrals.csv` with the integrals over the patch, the values at the brane and at the tip, and check columns of the solver.

Why the profiles can be compared with the field equations directly. The field equations use $T^{\mu}{}_{\nu}$ with one index up and one down. In the frame of rulers (the diagonal vielbein of Chapter 6) a component is $T^{a}{}_{b} = e^{a}{}_{\mu}\, e_{b}{}^{\nu}\, T^{\mu}{}_{\nu}$, and for a diagonal vielbein a diagonal component picks up one factor and its inverse: $T^{a}{}_{a} = T^{\mu}{}_{\mu}$ (no sum). So the proper densities of the profiles are exactly the ρ, p_3, p_t, p_0 of the field equations.

The Kohn-Sham source in words. The record `Revision/kohn_sham/ks-theory.json` (key `emt`) gives the four components as sums over the occupied orbitals. Two facts matter here. First, $p_t = e_{\text{int}}$, the interaction energy density: in the good sector no orbital moves along the extra times, so there is no extra-time kinetic pressure; for $\lambda = 0$ the interaction vanishes and $p_t = 0$ exactly. Second, p_3 is the kinetic pressure of the motion along 3-space plus e_{int}, so for a gas whose quanta move along 3-space p_3 is in general not zero; for the recorded states with $\lambda = 0$ its integral over the patch is positive at every slice (Notebook 17a, In [16] and figure 7). The mixed component, there written $T^{x_4}{}_{y}$, vanishes for every eigen-orbital (key `emt.offDiagonal`), so the Kohn-Sham states

meet the part $q_{40} = q_{04} = 0$ of C1. The question is the dependence on x_0, and conditions C2 and C3.

The integral over the patch. A small region of the hidden direction between y and $y + dy$, times the coordinate box of 3-space and of the extra times, has the proper 7-volume

$$dV_7 = \sqrt{|g|}\; d^3x\, d^3x_t\, dy = e^{6Hy}\, \ell^3 v_t\, dy = \mathrm{Vol}_7\, e^{6Hy}\, dy$$

(rule: in the coordinate y the product of the seven scale factors other than that of the time is $(e^{a_4}e^{Hy})^3(e^{-a_4}e^{Hy})^3 \cdot 1 = e^{6Hy}$, Chapter 14; the coordinate box of 3-space is a cube of side ℓ and that of the extra times has the coordinate volume v_t). The runs use $\ell = 8\pi$ (from the momentum spacing $\Delta k = 2\pi/\ell = 0.25$) and $v_t = 1$, so $\mathrm{Vol}_7 = (8\pi)^3 = 512\pi^3 \approx 15875.2$ (record `parameters.json`, key `physics.Vol7`). The total amount of a density X in the patch and its mirror copy is therefore

$$\int X \;=\; 2\,\mathrm{Vol}_7 \int_{-3}^{0} e^{6Hy}\, X(y)\, dy,$$

the columns `int_rho`, `int_p3`, `int_p_t`, `int_p0` of the table. The factor 2 counts the mirror copy of the ASSUMED Z2 brane. For $X = \rho$ the integral is the energy E of the Kohn-Sham state (`ks-theory.json`, key `emt.integrated`). The proper volume of the patch and its copy is

$$2\,\mathrm{Vol}_7 \int_{-L}^{0} e^{6Hy}\, dy = 2\,\mathrm{Vol}_7 \left[\frac{e^{6Hy}}{6H}\right]_{-L}^{0} = 2\,\mathrm{Vol}_7\, \frac{1 - e^{-6HL}}{6H}$$

(rule: an antiderivative of e^{cy} is e^{cy}/c; then the fundamental theorem of calculus, upper value minus lower value, with $e^0 = 1$). The **weighted mean** of X is the amount divided by the volume:

$$\bar{X} = \frac{\int X}{2\,\mathrm{Vol}_7\,(1 - e^{-6HL})/(6H)}.$$

Note how fast the weight e^{6Hy} falls toward the tip: at $y = -L = -3$ (with $H = 1$) it is $e^{-18} \approx 1.5 \times 10^{-8}$.

The prediction of the conditions. C1 asks for flat profiles, C2 for $V = 0$ at every point (or, averaged, $R = 1$), C3 for a constant $\int \rho$ along the history and equal pressures. Notebook 17a checks each against the record.

17.8 Example: the three conditions tested on 75 recorded ground states

The first notebook derives the three conditions from the Lovelock components stored in the record, with exact computer algebra; reads the 75 recorded ground states; and reproduces every number of the five checks on the Kohn-Sham states of `Revision/field_equations_a4/reports/ks-source-conditions.json` (its sixth check, `ks_verdict_holds_for_every_b4`, is about the metric with b_4). It prints 16 PASS lines and draws seven figures: the hidden coordinate and the energy profiles; a heat map of the spread of ρ (C1); the violation profiles and a heat map of their size (C2);

three points of one state as bars; the averaged ratio R; and the integrals along the history (C3). It runs in about 15 seconds on a typical laptop and needs no Rust.

17.9 How to run Notebook 17a

Step 1. What this notebook does and what it needs.

Notebook 17a (The source conditions of the a4 equations on the recorded Kohn-Sham states) is the file `Revision/textbook/notebooks/17a_source_conditions.ipynb` of the repository Dirac_claude. It derives with sympy, from the Lovelock components stored in the Revision record of the a4 field equations, the three conditions that every source of the author's metric must meet (C1: no dependence on the hidden coordinate x0; C2: p3 + p_t = 2 p0; C3: for the linear member a4 = A H x4, equal pressures and a constant energy density). It then evaluates the three conditions on the 75 committed Kohn-Sham ground states of dirac16complex, reproduces every number of the five checks of the Revision record ks-source-conditions.json, shows that no recorded Kohn-Sham ground state is an admissible source, so that the Kohn-Sham history is a prescribed background, and draws seven teaching plots. It needs a computer with Windows 11, macOS or Linux, an internet connection for the installation, the program Git, and Python 3.12 or newer (the notebooks were built with Python 3.14.5) with these packages at exactly these versions: numpy 2.4.6, sympy 1.14.0, mpmath 1.3.0, matplotlib 3.11.0, jupyterlab 4.4.10, nbformat 5.10.4, nbclient 0.10.2, ipykernel 7.1.0 and nbconvert 7.16.6. The notebook itself imports numpy, sympy and matplotlib; the other packages run Jupyter, the program that shows and runs notebooks. It does not need Rust.

Step 2. Install Git and Python (once per computer).

A terminal is the window in which you type commands: on Windows the app Windows PowerShell (or Terminal), on macOS the app Terminal (it runs the shell zsh), on Linux any terminal (it runs the shell bash). Type every command of this section into a terminal exactly as printed, one line at a time, and press Enter after each line.

Windows: download Git from https://git-scm.com/download/win and install it with the default choices. Download Python from https://www.python.org/downloads/ and run the installer; in its first window tick the box "Add python.exe to PATH" before you click "Install Now".

macOS: download Python from https://www.python.org/downloads/ and run the installer. Then open the app Terminal and run this command, which installs Git and the compiler tools:

macOS (zsh):

```
xcode-select --install
```

Linux (Debian or Ubuntu; other distributions have packages of the same names): run these two commands:

Linux (bash):

```
sudo apt update
sudo apt install git python3 python3-venv
```

Then close the terminal and open a NEW one (a terminal opened before the installation does not know the new programs), and check the version of Python; it must print 3.12 or a higher number:

Windows (PowerShell):

```
py -3 --version
```

macOS (zsh) and Linux (bash):

```
python3 --version
```

If an older Linux prints a lower number (Ubuntu 22.04 has Python 3.10), install Python 3.12 with the following three commands, and in Step 3 type `python3.12` instead of `python3` in the command that creates the environment:

Linux (bash), only when the version is too low:

```
sudo add-apt-repository ppa:deadsnakes/ppa
sudo apt update
sudo apt install python3.12 python3.12-venv
```

Step 3. Get the repository and install the packages (once per computer).

The commands below download the repository (a few hundred megabytes; the folder then needs up to about 1 GB of disk space) into the folder Dirac_claude inside your home folder, create a private Python environment in the folder dirac-book-env inside your home folder (a private environment is a folder with its own copy of Python and of the packages, so that nothing else on your computer is changed), activate it (from then on the commands `python` and `jupyter` typed in this terminal are those of the environment, and the prompt starts with (dirac-book-env)), and install the packages at the pinned versions (this downloads about 90 MB and takes a few minutes; the environment takes about 400 MB of disk space). If you have done this step before, for this or for another notebook, skip it and go to Step 4; to get the newest version of the repository, run `git pull` in the repository folder after Step 4.

Windows (PowerShell):

```
cd $HOME
git clone https://github.com/once-ere/Dirac_claude.git
py -3 -m venv "$HOME\dirac-book-env"
Set-ExecutionPolicy -ExecutionPolicy RemoteSigned -Scope Process -Force
& "$HOME\dirac-book-env\Scripts\Activate.ps1"
python -m pip install --upgrade pip
python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
```

The line with `Set-ExecutionPolicy` allows PowerShell to run the activation script in this one window only; it changes nothing permanently.

macOS (zsh):

```
cd ~
git clone https://github.com/once-ere/Dirac_claude.git
python3 -m venv ~/dirac-book-env
source ~/dirac-book-env/bin/activate
python -m pip install --upgrade pip
python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
```

Linux (bash):

```
cd ~
git clone https://github.com/once-ere/Dirac_claude.git
python3 -m venv ~/dirac-book-env
source ~/dirac-book-env/bin/activate
python -m pip install --upgrade pip
python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
```

Step 4. In every new terminal: activate the environment and go into the repository folder.

Every later step starts in the repository folder with the environment active. Run these lines whenever you open a new terminal (they do no harm if the environment is already active):

Windows (PowerShell):

```
Set-ExecutionPolicy -ExecutionPolicy RemoteSigned -Scope Process -Force
& "$HOME\dirac-book-env\Scripts\Activate.ps1"
cd "$HOME\Dirac_claude"
```

macOS (zsh) and Linux (bash):

```
source ~/dirac-book-env/bin/activate
cd ~/Dirac_claude
```

Step 5. Run the notebook in JupyterLab.

In the repository folder, with the environment active, run these two lines (the first one goes into the folder of the notebooks):

Windows, macOS and Linux:

```
cd Revision/textbook/notebooks
jupyter lab 17a_source_conditions.ipynb
```

JupyterLab opens in your web browser and shows the notebook (if no browser window opens, copy the address that starts with `http://localhost:8888/lab` from the terminal into the address bar

of your browser). The name at the top right of the notebook must read Python 3 (ipykernel). Choose the menu Run > Run All Cells. While a cell runs, the label to its left shows `[*]`; when it has finished, the label shows a number. The notebook has finished when the last code cell shows a number; this takes about 15 seconds on a typical laptop. Scroll to the end and compare the last printed lines with the lines in the step "What the notebook writes and what you must see" below. To keep the results, save the notebook (menu File > Save Notebook). To stop JupyterLab, choose the menu File > Shut Down, or press Ctrl+C twice in the terminal.

Step 6. Or run the notebook without a browser (headless).

In the repository folder, with the environment active, run:

Windows, macOS and Linux:

```
cd Revision/textbook/notebooks
jupyter nbconvert --to notebook --execute --inplace 17a_source_conditions.ipynb
```

This runs every cell from the top to the bottom and saves the results into the notebook file. A failed check stops it with an error message that contains AssertionError and the name of the check. If the command ends with a line that starts with `[NbConvertApp] Writing` and shows no error, every check passed; open the notebook with `jupyter lab 17a_source_conditions.ipynb` (in the same folder, without running the cells again) to read the printed lines and see the figures.

Step 7. What the notebook writes and what you must see.

The notebook writes (or overwrites) these files:

- `Revision/textbook/figures/17a.captions.json`
- `Revision/textbook/figures/17a_1_rho_profiles.png`
- `Revision/textbook/figures/17a_2_c1_map.png`
- `Revision/textbook/figures/17a_3_violation_profiles.png`
- `Revision/textbook/figures/17a_4_c2_map.png`
- `Revision/textbook/figures/17a_5_three_points.png`
- `Revision/textbook/figures/17a_6_integrated_ratio.png`
- `Revision/textbook/figures/17a_7_history_integrals.png`

It changes no other file of the repository; running it headless or saving it in JupyterLab also rewrites the notebook file itself. It does not use the internet while it runs. The files it writes are the same files that are stored in the repository (on another computer a figure may differ in a few bytes, which is harmless). To get the stored versions back, run this command in the repository folder (it also undoes every change you made yourself in the folder Revision/textbook):

Windows, macOS and Linux:

```
git checkout -- Revision/textbook
```

Every check of the notebook prints a line that starts with PASS. At the end of the notebook (the output of its last code cell) you must see exactly these lines:

```
PASS every figure file of this notebook exists
ALL 16 CHECKS PASSED (notebook 17a)
```

and the notebook must show 7 figures below the cells that draw them.

Step 8. If something goes wrong.

- "ModuleNotFoundError: No module named ..." in the notebook: JupyterLab was started without the environment. Stop it (menu File > Shut Down), do Step 4, and start it again. If the error remains, another Python installation has registered its own kernel called python3; with the environment active, run the following command and start JupyterLab again:

```
python -m ipykernel install --user --name python3
```

- "FileNotFoundError: The repository folder was not found": the notebook was opened from a copy outside the repository. Open the file `Revision/textbook/notebooks/17a_source_conditions.ipynb` inside the folder Dirac_claude.
- "fatal: destination path 'Dirac_claude' already exists" in Step 3: the repository was downloaded before; skip the line with `git clone`.
- Windows: "running scripts is disabled on this system": run the line with `Set-ExecutionPolicy` and then the activation line again. "py is not recognized": use `python` instead of `py -3`; "python is not recognized": install Python again and tick "Add python.exe to PATH".
- Linux: "ensurepip is not available" when the environment is created: run `sudo apt install python3-venv` and repeat Step 3.
- "jupyter is not recognized" or "command not found: jupyter": the environment is not active; do Step 4. If the environment is active and the message stays, the programs jupyter-lab and jupyter-nbconvert are not in the folders where the terminal looks for programs (`python -m jupyter` does not help then: it has to find the same programs). Start them through Python itself, in the folder of the notebook: the first command below does what `jupyter lab` does, the second what the headless command does:

```
python -m jupyterlab 17a_source_conditions.ipynb
python -m nbconvert --execute --inplace 17a_source_conditions.ipynb
```

- Windows: the headless run prints a RuntimeWarning that mentions the "Proactor event loop" and zmq: this is a message of the package pyzmq, not an error; the run continues normally.
- A red box with "Matplotlib is building the font cache; this may take a moment." in the first run after the installation: this is a message, not an error; the run continues and the message does not come again.

- An AssertionError names a check that failed: choose the menu Kernel > Restart Kernel and Run All Cells; if it fails again, install the packages again with the pip commands of Step 3, because a different package version can change the last digits of a result.
- "FileNotFoundError" naming ks-source-conditions.json or a profile file: the notebook reads the Revision records of the repository. Run it inside the folder Revision/textbook/notebooks of a complete copy of the repository made with git clone, not on a copy of the notebook file alone.

17.10 Notebook 17a: complete text

This section prints the complete text of the notebook file `Revision/textbook/notebooks/17a_source_conditions.ipynb`: every cell in order, with the output that the stored, executed notebook holds. A text cell (Jupyter calls it a markdown cell) is printed in a frame after the label Text cell. A code cell is printed after the label In [k], where k is the number that Jupyter gives the cell when it runs it; the text that the cell prints follows after the label Out [k], and every figure that the cell draws follows as a figure with its caption.

Text cell:

```
## 1. What this notebook computes

The author's metric has one free function, $a_4(x_4)$, and the Einstein-Lovelock
field equations decide which **source** (energy density and pressures of matter)
can produce it. The Revision record of these equations shows that their left-hand
sides do not depend on the hidden coordinate $x_0$ and obey one algebraic identity.
So every admissible source must satisfy three conditions:

- **C1**: no component of the source depends on $x_0$ (and the mixed components
  $q_{40}$ and $q_{04}$ are zero);
- **C2**: $p_3 + p_t = 2p_0$ (3-space pressure plus extra-time pressure equals
  twice the hidden-direction pressure);
- **C3**: for the linear member $a_4 = AHx_4 + a_0$ (the history used by the
  Kohn-Sham computations): $p_3 = p_t = p_0$ and a constant energy density.

This notebook

- derives C1, C2 and C3 with sympy from the Lovelock components of the record;
- reads the 75 Kohn-Sham ground states of the Revision record (their profiles
  along the hidden coordinate and their integrals);
- evaluates C1, C2 (point by point and after integration over $x_0$) and C3 on
  every state and reproduces every number of the five checks of the record
  `ks-source-conditions.json`;
- concludes, as the record does, that no recorded Kohn-Sham ground state is an
  admissible source, so that the Kohn-Sham history $a_4 = AHx_4$ is a
  **prescribed background** (the gas is a test field without back-reaction);
- draws seven teaching plots. It takes about fifteen seconds.
```

Text cell:

```
## 2. How to run this notebook
```

Step 1. What this notebook does and what it needs.

Notebook 17a (The source conditions of the a4 equations on the recorded Kohn-Sham states) is the file ‘Revision/textbook/notebooks/17a_source_conditions.ipynb‘ of the repository Dirac_claude. It derives with sympy, from the Lovelock components stored in the Revision record of the a4 field equations, the three conditions that every source of the author’s metric must meet (C1: no dependence on the hidden coordinate x0; C2: p3 + p_t = 2 p0; C3: for the linear member a4 = A H x4, equal pressures and a constant energy density). It then evaluates the three conditions on the 75 committed Kohn-Sham ground states of dirac16complex, reproduces every number of the five checks of the Revision record ks-source-conditions.json, shows that no recorded Kohn-Sham ground state is an admissible source, so that the Kohn-Sham history is a prescribed background, and draws seven teaching plots. It needs a computer with Windows 11, macOS or Linux, an internet connection for the installation, the program Git, and Python 3.12 or newer (the notebooks were built with Python 3.14.5) with these packages at exactly these versions: numpy 2.4.6, sympy 1.14.0, mpmath 1.3.0, matplotlib 3.11.0, jupyterlab 4.4.10, nbformat 5.10.4, nbclient 0.10.2, ipykernel 7.1.0 and nbconvert 7.16.6. The notebook itself imports numpy, sympy and matplotlib; the other packages run Jupyter, the program that shows and runs notebooks. It does not need Rust.

Step 2. Install Git and Python (once per computer).

A terminal is the window in which you type commands: on Windows the app Windows PowerShell (or Terminal), on macOS the app Terminal (it runs the shell zsh), on Linux any terminal (it runs the shell bash). Type every command of this section into a terminal exactly as printed, one line at a time, and press Enter after each line.

Windows: download Git from https://git-scm.com/download/win and install it with the default choices. Download Python from https://www.python.org/downloads/ and run the installer; in its first window tick the box "Add python.exe to PATH" before you click "Install Now".

macOS: download Python from https://www.python.org/downloads/ and run the installer. Then open the app Terminal and run this command, which installs Git and the compiler tools:

macOS (zsh):

```
xcode-select --install
```

Linux (Debian or Ubuntu; other distributions have packages of the same names): run these two commands:

Linux (bash):

```
sudo apt update
sudo apt install git python3 python3-venv
```

Then close the terminal and open a NEW one (a terminal opened before the installation does not know the new programs), and check the version of Python; it must print 3.12 or a higher number:

Windows (PowerShell):

```
py -3 --version
```

macOS (zsh) and Linux (bash):

```
python3 --version
```

If an older Linux prints a lower number (Ubuntu 22.04 has Python 3.10), install Python 3.12 with the following three commands, and in Step 3 type ‘python3.12‘ instead of ‘python3‘ in the command that creates the environment:

Linux (bash), only when the version is too low:

```
sudo add-apt-repository ppa:deadsnakes/ppa
sudo apt update
sudo apt install python3.12 python3.12-venv
```

Step 3. Get the repository and install the packages (once per computer).

The commands below download the repository (a few hundred megabytes; the folder then needs up to about 1 GB of disk space) into the folder Dirac_claude inside your home folder, create a private Python environment in the folder dirac-book-env inside your home folder (a private environment is a folder with its own copy of Python and of the packages, so that nothing else on your computer is changed), activate it (from then on the commands ‘python‘ and ‘jupyter‘ typed in this terminal are those of the environment, and the prompt starts with (dirac-book-env)), and install the packages at the pinned versions (this downloads about 90 MB and takes a few minutes; the environment takes about 400 MB of disk space). If you have done this step before, for this or for another notebook, skip it and go to Step 4; to get the newest version of the repository, run ‘git pull‘ in the repository folder after Step 4.

Windows (PowerShell):

```
cd $HOME
git clone https://github.com/once-ere/Dirac_claude.git
py -3 -m venv "$HOME\dirac-book-env"
Set-ExecutionPolicy -ExecutionPolicy RemoteSigned -Scope Process -Force
& "$HOME\dirac-book-env\Scripts\Activate.ps1"
python -m pip install --upgrade pip
python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
```

The line with ‘Set-ExecutionPolicy‘ allows PowerShell to run the activation script in this one window only; it changes nothing permanently.

macOS (zsh):

```
cd ~
git clone https://github.com/once-ere/Dirac_claude.git
python3 -m venv ~/dirac-book-env
source ~/dirac-book-env/bin/activate
python -m pip install --upgrade pip
python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
```

Linux (bash):

```
cd ~
git clone https://github.com/once-ere/Dirac_claude.git
python3 -m venv ~/dirac-book-env
source ~/dirac-book-env/bin/activate
python -m pip install --upgrade pip
python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
```

Step 4. In every new terminal: activate the environment and go into the repository folder.

Every later step starts in the repository folder with the environment active. Run these lines whenever you open a new terminal (they do no harm if the environment is already active):

Windows (PowerShell):

```
Set-ExecutionPolicy -ExecutionPolicy RemoteSigned -Scope Process -Force
& "$HOME\dirac-book-env\Scripts\Activate.ps1"
cd "$HOME\Dirac_claude"
```

macOS (zsh) and Linux (bash):

```
source ~/dirac-book-env/bin/activate
cd ~/Dirac_claude
```

Step 5. Run the notebook in JupyterLab.

In the repository folder, with the environment active, run these two lines (the first one goes into the folder of the notebooks):

Windows, macOS and Linux:

```
cd Revision/textbook/notebooks
jupyter lab 17a_source_conditions.ipynb
```

JupyterLab opens in your web browser and shows the notebook (if no browser window opens, copy the address that starts with ‘http://localhost:8888/lab‘ from the terminal into the address bar of your browser). The name at the top right of the notebook must read Python 3 (ipykernel). Choose the menu Run > Run All Cells. While a cell runs, the label to its left shows ‘[*]‘; when it has finished, the label shows a number. The notebook has finished when the last code cell shows a number; this takes about 15 seconds on a typical laptop. Scroll to the end and compare the last printed lines with the lines in the step "What the notebook writes and what you must see" below. To keep the results, save the notebook (menu File > Save Notebook). To stop JupyterLab, choose the menu File > Shut Down, or press Ctrl+C twice in the terminal.

Step 6. Or run the notebook without a browser (headless).

In the repository folder, with the environment active, run:

Windows, macOS and Linux:

```
cd Revision/textbook/notebooks
jupyter nbconvert --to notebook --execute --inplace 17a_source_conditions.ipynb
```

This runs every cell from the top to the bottom and saves the results into the notebook file. A failed check stops it with an error message that contains AssertionError and the name of the check. If the command ends with a line that starts with ‘[NbConvertApp] Writing‘ and shows no error, every check passed; open the notebook with ‘jupyter lab 17a_source_conditions.ipynb‘ (in the same folder, without running the cells again) to read the printed lines and see the figures.

Step 7. What the notebook writes and what you must see.

The notebook writes (or overwrites) these files:

- ‘Revision/textbook/figures/17a.captions.json‘
- ‘Revision/textbook/figures/17a_1_rho_profiles.png‘
- ‘Revision/textbook/figures/17a_2_c1_map.png‘
- ‘Revision/textbook/figures/17a_3_violation_profiles.png‘
- ‘Revision/textbook/figures/17a_4_c2_map.png‘
- ‘Revision/textbook/figures/17a_5_three_points.png‘
- ‘Revision/textbook/figures/17a_6_integrated_ratio.png‘
- ‘Revision/textbook/figures/17a_7_history_integrals.png‘

It changes no other file of the repository; running it headless or saving it in JupyterLab also rewrites the notebook file itself. It does not use the internet while it runs. The files it writes are the same files that are stored in the repository (on another computer a figure may differ in a few bytes, which is harmless). To get the stored versions back, run this command in the repository folder (it also undoes every change you made yourself in the folder Revision/textbook):

Windows, macOS and Linux:

```
git checkout -- Revision/textbook
```

Every check of the notebook prints a line that starts with PASS. At the end of the notebook (the output of its last code cell) you must see exactly these lines:

```
PASS every figure file of this notebook exists
ALL 16 CHECKS PASSED (notebook 17a)
```

and the notebook must show 7 figures below the cells that draw them.

Step 8. If something goes wrong.

- "ModuleNotFoundError: No module named ..." in the notebook: JupyterLab was started without the environment. Stop it (menu File > Shut Down), do Step 4, and start it again. If the error remains, another Python installation has registered its own kernel called python3; with the environment active, run the following command and start JupyterLab again:

  ```
  python -m ipykernel install --user --name python3
  ```

- "FileNotFoundError: The repository folder was not found": the notebook was opened from a copy outside the repository. Open the file ‘Revision/textbook/notebooks/17a_source_conditions.ipynb‘ inside the folder Dirac_claude.
- "fatal: destination path ’Dirac_claude’ already exists" in Step 3: the repository was downloaded before; skip the line with ‘git clone‘.
- Windows: "running scripts is disabled on this system": run the line with ‘Set-ExecutionPolicy‘ and then the activation line again. "py is not recognized": use ‘python‘ instead of ‘py -3‘; "python is not recognized": install Python again and tick "Add python.exe to PATH".
- Linux: "ensurepip is not available" when the environment is created: run ‘sudo apt install python3-venv‘ and repeat Step 3.
- "jupyter is not recognized" or "command not found: jupyter": the environment is not active; do Step 4. If the environment is active and the message stays, the programs jupyter-lab and jupyter-nbconvert are not in the folders where the terminal looks for programs (‘python -m jupyter‘ does not help then: it has to find the same programs). Start them through Python itself, in the folder of the notebook: the first command below does what ‘jupyter lab‘ does, the second what the headless command does:

    ```
    python -m jupyterlab 17a_source_conditions.ipynb
    python -m nbconvert --execute --inplace 17a_source_conditions.ipynb
    ```

- Windows: the headless run prints a RuntimeWarning that mentions the "Proactor event loop" and zmq: this is a message of the package pyzmq, not an error; the run continues normally.
- A red box with "Matplotlib is building the font cache; this may take a moment." in the first run after the installation: this is a message, not an error; the run continues and the message does not come again.
- An AssertionError names a check that failed: choose the menu Kernel > Restart Kernel and Run All Cells; if it fails again, install the packages again with the pip commands of Step 3, because a different package version can change the last digits of a result.
- "FileNotFoundError" naming ks-source-conditions.json or a profile file: the notebook reads the Revision records of the repository. Run it inside the folder Revision/textbook/notebooks of a complete copy of the repository made with git clone, not on a copy of the notebook file alone.

The first code cell below (the set-up cell) repeats these instructions as comments; then it imports the packages, finds the repository folder and defines the helpers ‘save_figure‘ (saves a figure and shows it), ‘check‘ (stops with an AssertionError when a check fails, prints a PASS line when it passes), ‘report‘ (prints a key number as a RESULT line) and ‘all_checks_passed‘ (prints the last line).

In [1]:

```
# HOW TO RUN NOTEBOOK 17a (the complete instructions)
#
# STEP 1. WHAT THIS NOTEBOOK DOES AND WHAT IT NEEDS.
#
# Notebook 17a (The source conditions of the a4 equations on the recorded Kohn-Sham
# states) is the file Revision/textbook/notebooks/17a_source_conditions.ipynb of the
# repository Dirac_claude. It derives with sympy, from the Lovelock components stored in
# the Revision record of the a4 field equations, the three conditions that every source
```

```
# of the author’s metric must meet (C1: no dependence on the hidden coordinate x0; C2: p3
# + p_t = 2 p0; C3: for the linear member a4 = A H x4, equal pressures and a constant
# energy density). It then evaluates the three conditions on the 75 committed Kohn-Sham
# ground states of dirac16complex, reproduces every number of the five checks of the
# Revision record ks-source-conditions.json, shows that no recorded Kohn-Sham ground
# state is an admissible source, so that the Kohn-Sham history is a prescribed
# background, and draws seven teaching plots. It needs a computer with Windows 11, macOS
# or Linux, an internet connection for the installation, the program Git, and Python 3.12
# or newer (the notebooks were built with Python 3.14.5) with these packages at exactly
# these versions: numpy 2.4.6, sympy 1.14.0, mpmath 1.3.0, matplotlib 3.11.0, jupyterlab
# 4.4.10, nbformat 5.10.4, nbclient 0.10.2, ipykernel 7.1.0 and nbconvert 7.16.6. The
# notebook itself imports numpy, sympy and matplotlib; the other packages run Jupyter,
# the program that shows and runs notebooks. It does not need Rust.
#
# STEP 2. INSTALL GIT AND PYTHON (ONCE PER COMPUTER).
#
# A terminal is the window in which you type commands: on Windows the app Windows
# PowerShell (or Terminal), on macOS the app Terminal (it runs the shell zsh), on Linux
# any terminal (it runs the shell bash). Type every command of this section into a
# terminal exactly as printed, one line at a time, and press Enter after each line.
#
# Windows: download Git from https://git-scm.com/download/win and install it with the
# default choices. Download Python from https://www.python.org/downloads/ and run the
# installer; in its first window tick the box "Add python.exe to PATH" before you click
# "Install Now".
#
# macOS: download Python from https://www.python.org/downloads/ and run the installer.
# Then open the app Terminal and run this command, which installs Git and the compiler
# tools:
#
# macOS (zsh):
#     xcode-select --install
#
# Linux (Debian or Ubuntu; other distributions have packages of the same names): run
# these two commands:
#
# Linux (bash):
#     sudo apt update
#     sudo apt install git python3 python3-venv
#
# Then close the terminal and open a NEW one (a terminal opened before the installation
# does not know the new programs), and check the version of Python; it must print 3.12 or
# a higher number:
#
# Windows (PowerShell):
#     py -3 --version
#
# macOS (zsh) and Linux (bash):
#     python3 --version
#
# If an older Linux prints a lower number (Ubuntu 22.04 has Python 3.10), install Python
# 3.12 with the following three commands, and in Step 3 type python3.12 instead of
# python3 in the command that creates the environment:
#
```

```
# Linux (bash), only when the version is too low:
#     sudo add-apt-repository ppa:deadsnakes/ppa
#     sudo apt update
#     sudo apt install python3.12 python3.12-venv
#
# STEP 3. GET THE REPOSITORY AND INSTALL THE PACKAGES (ONCE PER COMPUTER).
#
# The commands below download the repository (a few hundred megabytes; the folder then
# needs up to about 1 GB of disk space) into the folder Dirac_claude inside your home
# folder, create a private Python environment in the folder dirac-book-env inside your
# home folder (a private environment is a folder with its own copy of Python and of the
# packages, so that nothing else on your computer is changed), activate it (from then on
# the commands python and jupyter typed in this terminal are those of the environment,
# and the prompt starts with (dirac-book-env)), and install the packages at the pinned
# versions (this downloads about 90 MB and takes a few minutes; the environment takes
# about 400 MB of disk space). If you have done this step before, for this or for another
# notebook, skip it and go to Step 4; to get the newest version of the repository, run
# git pull in the repository folder after Step 4.
#
# Windows (PowerShell):
#     cd $HOME
#     git clone https://github.com/once-ere/Dirac_claude.git
#     py -3 -m venv "$HOME\dirac-book-env"
#     Set-ExecutionPolicy -ExecutionPolicy RemoteSigned -Scope Process -Force
#     & "$HOME\dirac-book-env\Scripts\Activate.ps1"
#     python -m pip install --upgrade pip
#     python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
#     python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
#     python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
#
# The line with Set-ExecutionPolicy allows PowerShell to run the activation script in
# this one window only; it changes nothing permanently.
#
# macOS (zsh):
#     cd ~
#     git clone https://github.com/once-ere/Dirac_claude.git
#     python3 -m venv ~/dirac-book-env
#     source ~/dirac-book-env/bin/activate
#     python -m pip install --upgrade pip
#     python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
#     python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
#     python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
#
# Linux (bash):
#     cd ~
#     git clone https://github.com/once-ere/Dirac_claude.git
#     python3 -m venv ~/dirac-book-env
#     source ~/dirac-book-env/bin/activate
#     python -m pip install --upgrade pip
#     python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
#     python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
#     python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
#
# STEP 4. IN EVERY NEW TERMINAL: ACTIVATE THE ENVIRONMENT AND GO INTO THE REPOSITORY
```

```
# FOLDER.
#
# Every later step starts in the repository folder with the environment active. Run these
# lines whenever you open a new terminal (they do no harm if the environment is already
# active):
#
# Windows (PowerShell):
#     Set-ExecutionPolicy -ExecutionPolicy RemoteSigned -Scope Process -Force
#     & "$HOME\dirac-book-env\Scripts\Activate.ps1"
#     cd "$HOME\Dirac_claude"
#
# macOS (zsh) and Linux (bash):
#     source ~/dirac-book-env/bin/activate
#     cd ~/Dirac_claude
#
# STEP 5. RUN THE NOTEBOOK IN JUPYTERLAB.
#
# In the repository folder, with the environment active, run these two lines (the first
# one goes into the folder of the notebooks):
#
# Windows, macOS and Linux:
#     cd Revision/textbook/notebooks
#     jupyter lab 17a_source_conditions.ipynb
#
# JupyterLab opens in your web browser and shows the notebook (if no browser window
# opens, copy the address that starts with http://localhost:8888/lab from the terminal
# into the address bar of your browser). The name at the top right of the notebook must
# read Python 3 (ipykernel). Choose the menu Run > Run All Cells. While a cell runs, the
# label to its left shows [*]; when it has finished, the label shows a number. The
# notebook has finished when the last code cell shows a number; this takes about 15
# seconds on a typical laptop. Scroll to the end and compare the last printed lines with
# the lines in the step "What the notebook writes and what you must see" below. To keep
# the results, save the notebook (menu File > Save Notebook). To stop JupyterLab, choose
# the menu File > Shut Down, or press Ctrl+C twice in the terminal.
#
# STEP 6. OR RUN THE NOTEBOOK WITHOUT A BROWSER (HEADLESS).
#
# In the repository folder, with the environment active, run:
#
# Windows, macOS and Linux:
#     cd Revision/textbook/notebooks
#     jupyter nbconvert --to notebook --execute --inplace 17a_source_conditions.ipynb
#
# This runs every cell from the top to the bottom and saves the results into the notebook
# file. A failed check stops it with an error message that contains AssertionError and
# the name of the check. If the command ends with a line that starts with [NbConvertApp]
# Writing and shows no error, every check passed; open the notebook with jupyter lab
# 17a_source_conditions.ipynb (in the same folder, without running the cells again) to
# read the printed lines and see the figures.
#
# STEP 7. WHAT THE NOTEBOOK WRITES AND WHAT YOU MUST SEE.
#
# The notebook writes (or overwrites) these files:
#
```

```
# - Revision/textbook/figures/17a.captions.json
# - Revision/textbook/figures/17a_1_rho_profiles.png
# - Revision/textbook/figures/17a_2_c1_map.png
# - Revision/textbook/figures/17a_3_violation_profiles.png
# - Revision/textbook/figures/17a_4_c2_map.png
# - Revision/textbook/figures/17a_5_three_points.png
# - Revision/textbook/figures/17a_6_integrated_ratio.png
# - Revision/textbook/figures/17a_7_history_integrals.png
#
# It changes no other file of the repository; running it headless or saving it in
# JupyterLab also rewrites the notebook file itself. It does not use the internet while
# it runs. The files it writes are the same files that are stored in the repository (on
# another computer a figure may differ in a few bytes, which is harmless). To get the
# stored versions back, run this command in the repository folder (it also undoes every
# change you made yourself in the folder Revision/textbook):
#
# Windows, macOS and Linux:
#     git checkout -- Revision/textbook
#
# Every check of the notebook prints a line that starts with PASS. At the end of the
# notebook (the output of its last code cell) you must see exactly these lines:
#
#     PASS every figure file of this notebook exists
#     ALL 16 CHECKS PASSED (notebook 17a)
#
# and the notebook must show 7 figures below the cells that draw them.
#
# STEP 8. IF SOMETHING GOES WRONG.
#
# - "ModuleNotFoundError: No module named ..." in the notebook: JupyterLab was started
#   without the environment. Stop it (menu File > Shut Down), do Step 4, and start it
#   again. If the error remains, another Python installation has registered its own
#   kernel called python3; with the environment active, run the following command and
#   start JupyterLab again:
#     python -m ipykernel install --user --name python3
# - "FileNotFoundError: The repository folder was not found": the notebook was opened
#   from a copy outside the repository. Open the file
#   Revision/textbook/notebooks/17a_source_conditions.ipynb inside the folder
#   Dirac_claude.
# - "fatal: destination path 'Dirac_claude' already exists" in Step 3: the repository was
#   downloaded before; skip the line with git clone.
# - Windows: "running scripts is disabled on this system": run the line with
#   Set-ExecutionPolicy and then the activation line again. "py is not recognized": use
#   python instead of py -3; "python is not recognized": install Python again and tick
#   "Add python.exe to PATH".
# - Linux: "ensurepip is not available" when the environment is created: run sudo apt
#   install python3-venv and repeat Step 3.
# - "jupyter is not recognized" or "command not found: jupyter": the environment is not
#   active; do Step 4. If the environment is active and the message stays, the programs
#   jupyter-lab and jupyter-nbconvert are not in the folders where the terminal looks for
#   programs (python -m jupyter does not help then: it has to find the same programs).
#   Start them through Python itself, in the folder of the notebook: the first command
#   below does what jupyter lab does, the second what the headless command does:
#     python -m jupyterlab 17a_source_conditions.ipynb
```

```
#     python -m nbconvert --execute --inplace 17a_source_conditions.ipynb
# - Windows: the headless run prints a RuntimeWarning that mentions the "Proactor event
#   loop" and zmq: this is a message of the package pyzmq, not an error; the run
#   continues normally.
# - A red box with "Matplotlib is building the font cache; this may take a moment." in
#   the first run after the installation: this is a message, not an error; the run
#   continues and the message does not come again.
# - An AssertionError names a check that failed: choose the menu Kernel > Restart Kernel
#   and Run All Cells; if it fails again, install the packages again with the pip
#   commands of Step 3, because a different package version can change the last digits of
#   a result.
# - "FileNotFoundError" naming ks-source-conditions.json or a profile file: the notebook
#   reads the Revision records of the repository. Run it inside the folder
#   Revision/textbook/notebooks of a complete copy of the repository made with git clone,
#   not on a copy of the notebook file alone.
#
# ------------------------------------------------------------------------------------
# ====================================================================================

Text cell:

```
## 3. The words used in this notebook

- **Coordinates** (the author's names): $x_1, x_2, x_3$ = ordinary 3-space,
  which inflates (scale factor $e^{a_4}\sin^{1/6}z$); $x_4$ = the time;
  $x_5, x_6, x_7$ = the three **extra times**, which **deflate exponentially**
  (scale factor $e^{-a_4}\sin^{1/6}z$, with $a_4$ increasing); $x_0$ = the hidden
  space direction, with $z = 6Hx_0$ between $0$ and $\pi/2$.
- **Hidden coordinate** $y = \ln(\sin z)/(6H)$: another way to number the points
  of the hidden direction. $y = 0$ is the end $z = \pi/2$ (the **brane**), and
  $y \to -\infty$ is the end $z \to 0$ (the **tip**). The computations stop at
  $y = -L = -3$ (the **tip cutoff**). Since $y$ grows when $x_0$ grows, "depends
  on $y$" and "depends on $x_0$" mean the same thing.
- **Energy-momentum tensor** $T^\mu{}_\nu$: an $8 \times 8$ table at each point
  that says how much energy and momentum matter has and how they flow. For our
  sources it is diagonal: $T = \mathrm{diag}(p_3, p_3, p_3, -\rho, p_t, p_t, p_t,
  p_0)$ in the order $x_0, \dots, x_7$, plus possible mixed entries $q_{40}$ (row
  $x_4$, column $x_0$) and $q_{04}$ (row $x_0$, column $x_4$).
```

```
- **Energy density** $\rho$ and **pressures** $p_3$ (each direction of 3-space),
  $p_t$ (each extra time), $p_0$ (the hidden direction).
- **Source**: the matter whose $T$ stands on the right-hand side of the field
  equations. **Admissible source**: a $T$ for which the field equations of the
  author's metric can hold.
- **Profile**: a component of $T$ as a function of $y$, stored at the 151 points
  $y = -3, -2.98, \dots, 0$. **Proper density**: per unit of proper 7-volume
  (the volume that rulers measure). The diagonal components $T^\mu{}_\mu$ (one
  index up, one down) are the same in the coordinates and in the frame of rulers,
  so the profiles are directly the $\rho$ and $p$ of the field equations.
- **Kohn-Sham state**: a many-fermion state of dirac16complex computed with the
  Kohn-Sham method (density functional theory) by the Rust solver of the Revision
  record. A state is labelled by its particle number $N$ (8, 136 or 688), its
  self-coupling $\lambda$ ($0$, $\pm\lambda_1$, $\pm\lambda_2$) and its **slice**
  $a_{4,0}$, the value of $a_4$ at which it was computed ($0, 0.5, 1, 1.5, 2$).
  The name `N136_lamp2_a20` means $N = 136$, $\lambda = +\lambda_2$,
  $a_{4,0} = 2.0$ (`lamm1` is $-\lambda_1$, `lam0` is $\lambda = 0$).
- **History**: the sequence of slices along $a_4 = AHx_4$ with $A = 1$.
  **Linear member**: this choice of $a_4$, a straight line in $x_4$.
- **Prescribed background**: a metric that is GIVEN, not solved for. A field that
  moves in it but whose own gravity is ignored is a **test field**; ignoring its
  gravity means ignoring its **back-reaction** on the metric.
- **Integral over the patch**: $2\,\mathrm{Vol}_7\int_{-3}^{0} e^{6Hy}\,X\,dy$, the
  total amount of $X$ in the computed region. Here $\mathrm{Vol}_7 = \ell^3 v_t$ is
  the coordinate volume of the six directions $x_1, x_2, x_3$ (a box of side
  $\ell$) and $x_5, x_6, x_7$ (coordinate volume $v_t$); times $e^{6Hy}\,dy$ it is
  the proper 7-volume of a thin slab of the hidden direction. The factor 2 counts
  the mirror copy of the ASSUMED $Z_2$ brane.
- **max|T|**: the largest absolute value of $\rho$, $p_3$, $p_t$, $p_0$ of a state
  over all $y$; we divide by it to compare states of very different size.
- **Status labels**: PROVED (exact), COMPUTED (numerical), ASSUMED (a choice),
  OPEN (not known).
- Units: $H = 1$, $m = 1$ (the fermion mass): lengths in units of $1/H$, energy
  densities and pressures in units of $m^8$, integrals over the patch (energies)
  in units of $m$.
```

Text cell:

```
## 4. The physical and mathematical situation

The author's metric (order $x_0, \dots, x_7$, $z = 6Hx_0$) is diagonal with entries
$e^{2a_4}\sin^{1/3}z$ (three times), $-1$, $-e^{-2a_4}\sin^{1/3}z$ (three times),
$\cot^2 z$. The Einstein-Lovelock field equations are

$$\sum_{k=1}^{3}\alpha_k E_{(k)}{}^{\mu}{}_{\nu} + \Lambda\,\delta^\mu_\nu =
\kappa\,T^\mu{}_\nu ,$$

with the Lovelock tensors $E_{(1)}$ (Einstein), $E_{(2)}$ (Gauss-Bonnet), $E_{(3)}$
(third order), couplings $\alpha_k$, cosmological constant $\Lambda$ and strength of
gravity $\kappa$. The Revision record gives every component of the left-hand side
as a polynomial in $a_4'$, $a_4''$ and $H$ (the prime is $d/dx_4$). The diagonal
components give four equations:
```

```
$$\textstyle\sum_k\alpha_kE_{(k)}{}^{x_4}{}_{x_4} + \Lambda = -\kappa\rho,\quad
\sum_k\alpha_kE_{(k)}{}^{x_1}{}_{x_1} + \Lambda = \kappa p_3,$$
$$\textstyle\sum_k\alpha_kE_{(k)}{}^{x_5}{}_{x_5} + \Lambda = \kappa p_t,\quad
\sum_k\alpha_kE_{(k)}{}^{x_0}{}_{x_0} + \Lambda = \kappa p_0 .$$

The left-hand sides contain no $x_0$, so the right-hand sides cannot either (C1).
The left-hand sides obey $E^{x_1}{}_{x_1} + E^{x_5}{}_{x_5} = 2E^{x_0}{}_{x_0}$
for every $k$; adding the $x_1$ and $x_5$ equations and subtracting twice the $x_0$
equation gives $\kappa(p_3 + p_t - 2p_0) = 0$ (C2; $\Lambda$ cancels because
$\Lambda + \Lambda - 2\Lambda = 0$). For $a_4 = AHx_4 + a_0$ we have $a_4' = AH$
(a constant) and $a_4'' = 0$; then the $x_1$, $x_5$ and $x_0$ left-hand sides
coincide and none of them changes with $x_4$ (C3).

The Kohn-Sham computations of the Revision record use exactly this linear member:
they solve the Kohn-Sham equations of dirac16complex at five slices $a_{4,0}$ of the
history $a_4 = Hx_4$ (instantaneous, adiabatic states, in the good sector without
extra-time momenta, with the ASSUMED $Z_2$ mirror at the brane and a tip cutoff at
$y = -3$). The question of this notebook: is the energy-momentum tensor of these
states an admissible source, so that the history would be a solution of the
coupled equations? The answer of the record is no; we check every number of it.
```

Text cell:

```
## 5. The Revision records and the helpers that read them

The next cell imports the packages and defines four helpers. ‘read_json‘ reads a
JSON file of the repository. ‘record_entry‘ finds a check by its name in a Revision
report. ‘reproduces‘ is a check that passes only when this notebook’s own result
holds AND the named checks of the report have the verdict PASS; it prints the
report file and the check names. ‘tex_number‘ writes a number in powers of ten for
the captions of the figures. The cell then reads the record on the Kohn-Sham
source conditions, prints its conclusion and checks that its six checks passed:
the five on the Kohn-Sham states, which this notebook reproduces, and the sixth,
‘ks_verdict_holds_for_every_b4‘, which states that the verdict holds for the
author’s metric with any second function $b_4(x_4)$ of 2026-10-14 (the conditions
C1 to C3 below are derived on the background $b_4 = 1$).
```

In [2]:

```
import csv  # reads tables stored as CSV files (comma-separated values)

import numpy as np  # arrays of numbers
import sympy as sp  # exact algebra with symbols

SOURCE_REPORT = "Revision/field_equations_a4/reports/ks-source-conditions.json"
EQUATIONS = "Revision/field_equations_a4/a4-equations.json"  # the a4 equations
PY_A4 = "Revision/field_equations_a4/reports/python-a4-report.json"  # sympy checks
WL_A4 = "Revision/field_equations_a4/reports/wolfram-a4-report.json"  # Wolfram
GROUND = "Revision/kohn_sham/results/ground"  # the 75 Kohn-Sham ground states

def read_json(relative):

```

Out [2]:

```
RESULT checks of the record ks-source-conditions.json = 6 of 6 PASS
its conclusion: No Kohn-Sham state recorded in Revision/kohn_sham is an admissible source
    of the author's metric: C1 and C2 fail for every nonzero state (C2 also after
    integration over x0), and the Kohn-Sham history uses the linear member as a
    prescribed background, without back-reaction.  With the metric of 2026-10-14 (b4[x4])
    C1 alone excludes every recorded state for every b4 (check
    ks_verdict_holds_for_every_b4); C2 is the b4 = 1 form.
PASS the record on the Kohn-Sham source conditions has 6 checks, all PASS
```

```
## 6. The three conditions, derived from the a4 equations

The record stores each Lovelock component as a formula in the Wolfram Language:
‘ad1‘ stands for $a_4’$, ‘ad2‘ for $a_4’’$, ‘^‘ for a power. The next cell turns
the components $x_1x_1$, $x_4x_4$, $x_5x_5$, $x_0x_0$ and $x_4x_0$ of
```

```
$E_{(1)}, E_{(2)}, E_{(3)}$ into sympy expressions and prints those of Einstein's
tensor $E_{(1)}$ (they are the left-hand sides of Einstein gravity).
```

In [3]:

```
equations = read_json(EQUATIONS)
ad1, ad2 = sp.symbols("ad1 ad2", real=True)  # a4' and a4'' (the record's names)
H = sp.symbols("H", positive=True)  # the constant H of the metric
NAMES = {"ad1": ad1, "ad2": ad2, "H": H}  # how the record's names become symbols

def parse(text):
    """A formula of the record (Wolfram Language text) as a sympy expression."""
    return sp.sympify(text.replace("^", "**"), locals=NAMES)

COMPONENTS = ("x1x1", "x4x4", "x5x5", "x0x0", "x4x0")
E = {k: {c: parse(equations["lovelockTensors"][f"E{k}"][c]["input"])
         for c in COMPONENTS}
     for k in (1, 2, 3)}  # E[k][component]: the Lovelock tensor of order k
for c in COMPONENTS:
    say(f"E_(1)^{c[:2]}_{c[2:]} = {E[1][c]}")
```

Out [3]:

```

E_(1)^x0_x0 = 15*H**2 - 3*ad1**2
E_(1)^x4_x0 = 0
```

Text cell:

```
The next cell checks the three conditions on the left-hand sides, for all three
Lovelock orders.

- C1: every component contains only the symbols $a_4'$, $a_4''$, $H$ (no $x_0$,
  not even through $\cot z$), and the mixed $x_4x_0$ and $x_0x_4$ components are
  zero, so the source must have $q_{40} = q_{04} = 0$.
- C2: $E^{x_1}{}_{x_1} + E^{x_5}{}_{x_5} - 2E^{x_0}{}_{x_0}$ expands to zero.
- C3: with $a_4'' = 0$ the $x_1$, $x_5$, $x_0$ components are equal, and the
  $x_4$ component contains $a_4'$ and $H$ only (constant when $a_4' = AH$).
```

## 7. The recorded Kohn-Sham states and the hidden coordinate

The next cell reads the 75 profile files of the record (one per state; columns
‘y‘, ‘rho‘, ‘p3‘, ‘p_t‘, ‘p0‘ among others), the table of integrals, and the
parameters of the computations. For every state it computes max|T|, the largest
absolute value of the four components, and sorts the states into those with a
nonzero tensor and those with $T = 0$ everywhere (no source at all). It also prints
what the Kohn-Sham theory record says about the mixed components (there written
$T^{x_4}{}_y$): they vanish for every eigen-orbital, so the Kohn-Sham states meet
the part $q_{40} = q_{04} = 0$ of C1; the question is the $x_0$ dependence.
```

In [5]:

```
COLUMNS = ("rho", "p3", "p_t", "p0")  # the four diagonal components of the source

```
The next cell draws the violation profiles $V(y)/\max|T|$ of the states with
$\lambda = 0$ for $N = 136$ (left) and $N = 688$ (right), at the five slices. The
vertical axis is **symmetric logarithmic**: logarithmic for large positive and
negative values, linear between $-10^{-7}$ and $10^{-7}$, so that both signs and
seven orders of magnitude are visible. The dashed line is the value $0$ that C2
demands. Before drawing, the cell counts how often each plotted profile changes
its sign between neighbouring grid points, and how large $|V|$ is at the tip and
at the brane; the caption quotes these numbers.
```

12. Condition C3: the linear member along the history

The Kohn-Sham history is the linear member $a_4 = AHx_4$ with $A = 1$. For it the field equations need $p_3 = p_t = p_0$ and a constant ρ (C3). The record tests this on the integrals of the six states $N = 136$ and $N = 688$ with $\lambda = 0$ at the slices 0, 1 and 2. The next cell prints their integrated ρ, p_3, p_t, checks that ρ changes from slice to slice and that $p_3 \ne p_t$ (with the record's tolerance), and that the record prints the same numbers.

Figure 17a.7 saved as Revision/textbook/figures/17a_7_history_integrals.png
```

Text cell:

```
The states $N = 8$ need a separate remark. They consist of the eight brane zero
modes, which have zero 3-momentum $k$. The slice $a_{4,0}$ enters the Kohn-Sham
equations only through the redshifted momentum $k e^{-a_{4,0}}$, while the proper
box stays the same (the exact rescaling identity of the Kohn-Sham record), so for
$k = 0$ nothing changes: these states are the same at every slice. The next cell
confirms that their profiles are identical at all five slices and that they have
$p_3 = p_t$; so they satisfy the part "constant $\rho$ and $p_3 = p_t$" of C3. They
are nevertheless not admissible: $p_0$ differs from $p_3$, and they fail C1 and C2
(the maps of sections 8 and 9).
```

## 13. The states with no source at all

Five states have $T = 0$ at every point: $N = 8$ with $\lambda = 0$ (zero modes
with zero energy and no interaction). Is "no source" admissible? In Einstein
gravity ($\alpha_1 = 1$, $\alpha_2 = \alpha_3 = 0$) the record's $x_4$ and $x_0$
equations read $3a_4'^2 + 21H^2 + \Lambda = -\kappa\rho$ and
$-3a_4'^2 + 15H^2 + \Lambda = \kappa p_0$. With $\rho = p_0 = 0$, subtracting the
second from the first gives $6a_4'^2 + 6H^2 = 0$, impossible for real $a_4'$ and
```

$H > 0$: the left side is a square times 6 plus a positive number. The next cell repeats this with sympy, from the record's text of the two equations (sympy is told that a_4' is real and H positive, and it decides that the difference is positive), and checks the list of zero states against the record.

In [19]:

```
kappa, rho, p0, Lam = sp.symbols("kappa rho p0 Lam", real=True)
NAMES.update({"kappa": kappa, "rho": rho, "p0": p0, "Lam": Lam})

```
## 15. What this notebook showed

- PROVED (exact algebra with sympy on the Lovelock components stored in the a4
  record): the left-hand sides of the Einstein-Lovelock equations of the author's
  metric are free of
  $x_0$ and have no $x_4x_0$ component (C1), obey
  $E^{x_1}{}_{x_1} + E^{x_5}{}_{x_5} = 2E^{x_0}{}_{x_0}$ for every order (C2:
  $p_3 + p_t = 2p_0$), and for the linear member need equal pressures and a
  constant energy density (C3).
- COMPUTED (the 75 recorded Kohn-Sham ground states; every number of the five
  checks of the record `ks-source-conditions.json` reproduced): every nonzero
  state depends on $x_0$ (the spread of $\rho$ is at least $0.0497$ of max|T|),
  violates C2 point by point (by $2.09$ to $3.99$ times max|T|) and after
  integration over $x_0$ (ratios between $0.107$ and $0.414$ instead of $1$), and
  along the history $\rho$ changes and $p_3 \ne p_t$. The $N = 8$ states do not
  change along the history, but they too fail C1 and C2.
- PROVED (Einstein gravity): $T = 0$ is not a solution for $H > 0$, so the five
  states without a source are not admissible either.
- Hence no recorded Kohn-Sham ground state is an admissible source (the 135
  thermal states of the canonical matrix store no profiles and are not tested).
  The Kohn-Sham history $a_4 = Hx_4$ is a PRESCRIBED BACKGROUND (ASSUMED, not
  solved for): the gas is a test field without back-reaction, and energies,
  pressures and equations of state computed along it are not consequences of the
  coupled field equations.
- WHY (worked out in Notebook 17b): every source of the field equations must be
  conserved, and for a conserved source C2 says exactly that $p_0$ does not
  change along $x_0$, while C3 says exactly that no energy is exchanged with the
  inflating 3-space and the deflating extra times ($p_3 = p_t$). The Kohn-Sham
  states obey the conservation law of the hidden direction at every point, and
  the energy law of the time direction only for the total energy of the patch;
  their $p_0$ varies strongly along $x_0$ and their $p_3$ exceeds $p_t$.
- NOT shown: that no state of dirac16complex could ever be a source of the
  author's metric, or what metric the Kohn-Sham gas would produce with
  back-reaction (OPEN).
```

17.11 Line-by-line walk-through of Notebook 17a

The notebook has 20 code cells, In [1] to In [20]. This section explains every line of every one of them, in order: a line or a small group of lines is quoted, then explained. Where a line repeats a pattern already explained, we say so and explain only what is new. Each figure is described after the cell that draws it.

In [1], the set-up cell. Every line that starts with `#` is a **comment**: Python skips it. The comment lines at the top of the cell are the complete run instructions of Section 17.9, so that the notebook file carries its own instructions even when it is copied without the book. The code starts after the comment line that announces THE SET-UP (the same in every notebook of this book; it computes no physics).

```
import json  # reads and writes JSON files (text files that hold names and numbers)
import os  # reads the environment variable TEXTBOOK_OUTPUT_ROOT (explained below)
import textwrap  # breaks long printed text into lines of at most 89 characters
from pathlib import Path  # file and folder paths that work on Windows, macOS and Linux
```

`import` loads a **module**, a part of Python or of an installed package, so that the code may use it. `json`, `os`, `textwrap` and `pathlib` come with Python. `from pathlib import Path` takes the single name `Path` out of the module `pathlib`; a `Path` is the address of a file or folder, written the same way on every operating system. The text after `#` on each line is a comment.

```
import matplotlib  # the plotting package
import matplotlib.pyplot as plt  # its drawing functions, called plt by convention
from IPython.display import Image, display  # shows a saved picture below a cell
```

These load the plotting package matplotlib, its drawing functions under the short name `plt`, and the two functions `Image` and `display` of IPython (the part of Jupyter that runs Python), which show a picture file below a cell.

```
NOTEBOOK_ID = "17a"  # this notebook: chapter 17, example a
```

A **variable** is a name for a value. This line gives the name `NOTEBOOK_ID` to the **string** (a text in quotation marks) `"17a"`. The figure files and the last line of the notebook are named after it.

```
def find_repository_root():
    """Return the repository folder (Dirac_claude).

    Jupyter runs a notebook in the folder that holds it.  Starting there, go up one
    folder at a time until a folder contains Revision/textbook/requirements.txt (the
    list of the book's packages); that folder is the repository."""
    here = Path.cwd().resolve()  # the folder in which this notebook runs
    for folder in [here, *here.parents]:  # this folder, its parent, its grandparent ...
        if (folder / "Revision" / "textbook" / "requirements.txt").is_file():
            return folder
    raise FileNotFoundError(
        "The repository folder was not found: open this notebook inside the folder "
        "Revision/textbook/notebooks of the repository Dirac_claude")
```

`def` defines a **function**: a named piece of code that runs each time it is called. The text in triple quotation marks under the `def` line is its **docstring**, a description that Python stores but does not run. `Path.cwd()` is the folder in which Jupyter runs the notebook, and `.resolve()` writes it as a complete address. `here.parents` lists the folders above it; `[here, *here.parents]` is a **list** (an ordered collection in square brackets) that starts with `here` and continues with those folders (the star unpacks one list into another). The `for` loop visits the folders one after the other. The operator `/` joins a folder and a name into a longer path, and `.is_file()` is true when that file exists. The first folder that contains `Revision/textbook/requirements.txt` is the repository, and `return` hands it back to the caller. If no folder does, `raise` stops the notebook with a `FileNotFoundError` whose message says what to do.

```
# The repository folder.  It is never printed: it differs from computer to computer,
# and the printed output of a notebook must not.
REPO = find_repository_root()
# Every file is WRITTEN below OUTPUT_ROOT.  OUTPUT_ROOT is the repository folder unless
# the environment variable TEXTBOOK_OUTPUT_ROOT names another folder; the book's
# checking tool sets it, so that a check run writes into a scratch folder instead.
OUTPUT_ROOT = Path(os.environ.get("TEXTBOOK_OUTPUT_ROOT", str(REPO)))
```

The first code line calls the function and names its result `REPO`. The second chooses where files are written: `os.environ` holds the **environment variables** of the program (named texts it receives from the computer), and `.get(name, default)` returns the value of `TEXTBOOK_OUTPUT_ROOT` if it is set and `str(REPO)` (the repository folder as a string) otherwise. When you run the notebook the variable is not set, so files go into the repository; the book's checking tool sets it to a scratch folder.

```
def repository_file(relative):
    """The path of the repository file relative, for READING (a Revision record)."""
    return REPO / relative

def output_file(relative):
    """The path at which to WRITE the repository file relative (its folder is made)."""
    path = OUTPUT_ROOT / relative
    path.parent.mkdir(parents=True, exist_ok=True)
    return path
```

Two small functions. `repository_file` gives the full path of a file of the repository, for reading a Revision record. `output_file` gives the full path at which to write a file; `path.parent.mkdir(parents=True, exist_ok=True)` first creates the folder of the file and every missing folder above it, and does nothing if they exist.

```
def say(text):
    """Print text in lines of at most 89 characters (the width of a page of the book)."""
    print(textwrap.fill(str(text), width=89, subsequent_indent="    "))
```

`say` prints a text in lines of at most 89 characters; `textwrap.fill` breaks the text at blanks and starts every line after the first with four blanks. That is why long printed lines of this notebook continue on an indented second line.

```
matplotlib.rcdefaults()  # ignore personal matplotlib settings: same figures everywhere
plt.rcParams.update({"figure.figsize": (7.0, 4.2), "font.size": 10.0,
                     "axes.grid": True, "grid.alpha": 0.3})
```

`matplotlib.rcdefaults()` returns to the built-in settings of matplotlib, so that the figures are the same on every computer. `plt.rcParams.update({...})` then sets the default size of a figure (7.0 by 4.2 inches), the size of its letters (10 points) and a faint grid (`grid.alpha` 0.3 means 30 per cent opaque). The braces make a **dictionary**: pairs `key:  value`.

```
FIGURE_FOLDER = "Revision/textbook/figures"  # where the figures are saved
CAPTION_FILE = f"{FIGURE_FOLDER}/{NOTEBOOK_ID}.captions.json"  # their captions
FIGURE_NUMBERS = {}  # figure name -> its number k (file name <id>_<k>_<name>.png)
CAPTIONS = {}  # figure file name -> caption, written to CAPTION_FILE after every figure
# Start with an empty captions file ({} is an empty JSON dictionary); save_figure fills
# it.  newline="\n" writes the same line ends on Windows, macOS and Linux.
output_file(CAPTION_FILE).write_text("{}\n", encoding="utf-8", newline="\n")
```

A string that starts with `f` is an **f-string**: a name in braces is replaced by its value, so `CAPTION_FILE` is `"Revision/textbook/figures/17a.captions.json"`. `FIGURE_NUMBERS` and `CAPTIONS` start as empty dictionaries. The last line writes an empty JSON dictionary and a line end into the captions file; `encoding="utf-8"` fixes how letters are stored as bytes and `newline="\n"` stores the same line end on every system.

```
def save_figure(fig, name, caption):
    """Save the figure fig as Revision/textbook/figures/<id>_<k>_<name>.png, record its
    caption in CAPTION_FILE, show the saved picture below the cell and close the figure.
    k counts the figures of the notebook 1, 2, 3, ...; a cell run again keeps its k."""
    number = FIGURE_NUMBERS.setdefault(name, len(FIGURE_NUMBERS) + 1)
    file_name = f"{NOTEBOOK_ID}_{number}_{name}.png"
    relative = f"{FIGURE_FOLDER}/{file_name}"
    # dpi=150: 150 dots per inch.  bbox_inches="tight": cut away the empty margin.
    # metadata={"Software": None}: no program name is stored in the PNG file, so that
    # every run writes exactly the same bytes.
    fig.savefig(output_file(relative), dpi=150, bbox_inches="tight",
                metadata={"Software": None})
    plt.close(fig)  # forget the figure, so that Jupyter does not draw it a second time
    CAPTIONS[file_name] = caption
    output_file(CAPTION_FILE).write_text(
        json.dumps(CAPTIONS, indent=1, sort_keys=True) + "\n", encoding="utf-8",
        newline="\n")
    display(Image(filename=str(output_file(relative))),
            metadata={"textbook_figure": file_name})  # the saved picture itself
    say(f"Figure {NOTEBOOK_ID}.{number} saved as {relative}")
```

`setdefault(name, value)` returns the number already stored for this figure name, or stores and returns `len(FIGURE_NUMBERS) + 1`, one more than the number of figures so far: the figures are numbered 1, 2, 3, and a cell run twice keeps its number. The file name joins the notebook id, the number and the name, for example `17a_1_rho_profiles.png`. `fig.savefig` writes a PNG picture with 150 dots per inch, cuts away the empty margin and stores no program name, so that two runs write the same bytes. `plt.close(fig)` removes the figure from memory, because Jupyter would

otherwise draw it a second time. The caption is stored, the whole dictionary is written to the captions file (`json.dumps` turns it into JSON text with sorted keys), `display(Image(...))` shows the saved picture below the cell, and the last line prints where it was saved.

```
PASSED = []  # the names of the checks that passed, in order

def check(condition, name, record=None):
    """A check.  If condition is False, stop with an AssertionError that names the
    check (an if statement is used instead of assert, because python -O would skip an
    assert).  Otherwise print "PASS <name>" and, when the check reproduces a Revision
    record, a second line naming the record file and its check."""
    if not condition:
        raise AssertionError(f"check failed: {name}")
    PASSED.append(name)
    say(f"PASS {name}")
    if record is not None:
        say(f"     reproduces {record}")
```

`PASSED` starts as an empty list. `check` is the function behind every check of the notebook. If `condition` is false, `raise AssertionError(...)` stops the notebook with an error that names the check. Otherwise the name is appended to `PASSED`, the line PASS name is printed, and, when `record` is given, a second line names the Revision record that the check reproduces. `record=None` makes that argument optional.

```
def report(label, value, unit=""):
    """Print a key number as a line "RESULT <label> = <value> <unit>"."""
    say(f"RESULT {label} = {value}" + (f" {unit}" if unit else ""))

def all_checks_passed():
    """Print the last line of the notebook: how many checks passed."""
    print(f"ALL {len(PASSED)} CHECKS PASSED (notebook {NOTEBOOK_ID})")

say(f"Set-up of notebook {NOTEBOOK_ID} complete: repository folder found, helpers "
    "defined.")
```

`report` prints a key number as a line that starts with RESULT; `(f" {unit}" if unit else "")` adds the unit only when one is given. `all_checks_passed` prints the last line of the notebook; `len(PASSED)` is the number of checks that passed. The last statement prints the one output line of In [1]: Set-up of notebook 17a complete.

In [2], the Revision records and the helpers that read them.

```
import csv  # reads tables stored as CSV files (comma-separated values)

import numpy as np  # arrays of numbers
import sympy as sp  # exact algebra with symbols
```

`csv` comes with Python and reads tables stored as text with commas between the entries. numpy (short name `np`) works with **arrays**, tables of numbers on which arithmetic acts entry by entry. sympy (short name `sp`) does exact algebra with symbols.

```
SOURCE_REPORT = "Revision/field_equations_a4/reports/ks-source-conditions.json"
EQUATIONS = "Revision/field_equations_a4/a4-equations.json"  # the a4 equations
PY_A4 = "Revision/field_equations_a4/reports/python-a4-report.json"  # sympy checks
WL_A4 = "Revision/field_equations_a4/reports/wolfram-a4-report.json"  # Wolfram
GROUND = "Revision/kohn_sham/results/ground"  # the 75 Kohn-Sham ground states
```

Five names for the Revision records used below: the record on the Kohn-Sham source conditions (the record this notebook reproduces), the record of the a_4 equations, its two verification reports (sympy and Wolfram), and the folder of the recorded Kohn-Sham ground states.

```
def read_json(relative):
    """Read a JSON file of the repository (a Revision record)."""
    return json.loads(repository_file(relative).read_text(encoding="utf-8"))

def record_entry(report_file, name):
    """The entry {name, verdict, detail} of a check of a report, None if absent."""
    for entry in read_json(report_file)["checks"]:
        if entry["name"] == name:
            return entry
    return None
```

`read_json` reads a JSON file of the repository as text and turns it into Python dictionaries and lists (`json.loads`). Every Revision report has a list `checks` whose entries have a `name`, a `verdict` (PASS or FAIL) and a `detail` text. `record_entry` walks through that list and returns the entry with the given name; `None` (Python's "nothing") if there is none.

```
def reproduces(condition, name, report_file, record_names):
    """A check that also requires the named checks of the report to be PASS."""
    found = all((record_entry(report_file, n) or {}).get("verdict") == "PASS"
                for n in record_names)
    names_text = ", ".join(record_names)  # the check names, separated by commas
    check(condition and found, name, record=f"{report_file}, check {names_text}")
```

`reproduces` is the check used whenever a result of the notebook reproduces a Revision record. `all(... for n in record_names)` is true when the expression holds for every name in the list. For one name, `record_entry(...) or {}` is the entry, or an empty dictionary if the entry is missing; `.get("verdict")` reads its verdict (or `None`). So `found` is true only when every named check of the report exists and has the verdict PASS. `", ".join(...)` joins the names with commas. The check passes only when the notebook's own `condition` holds AND the record agrees; its second printed line names the report and the checks.

```
def tex_number(value, digits=2):
    """A number for a caption in powers of ten: 0.0123 -> 1.2 \\times 10^{-2}."""
    mantissa, exponent = f"{value:.{digits - 1}e}".split("e")
    return f"{mantissa} \\times 10^{{{int(exponent)}}}"
```

`tex_number` writes a number in powers of ten for the captions. The format `.1e` (here `digits - 1 = 1`) writes `0.0123` as `1.2e-02`; `.split("e")` cuts this text at the letter e into `"1.2"` and `"-02"`; `int("-02")` is the whole number -2. The result is the text `1.2 \times 10^{-2}`, which the book prints as 1.2×10^{-2}. (In a Python string a backslash is written twice, and in an f-string a brace is written twice, so `{{{...}}}` gives one literal brace around the value.)

```
source_record = read_json(SOURCE_REPORT)
summary = source_record["summary"]  # how many checks the record has, how many pass
passed, total = summary["pass"], summary["checks"]
report("checks of the record ks-source-conditions.json", f"{passed} of {total} PASS")
say("its conclusion: " + source_record["conclusion"])
check(summary == {"checks": 6, "pass": 6, "fail": 0},
      "the record on the Kohn-Sham source conditions has 6 checks, all PASS")
```

The record is read; its `summary` dictionary says how many checks it has and how many passed. `passed, total = a, b` gives two names at once. The cell prints the count and the record's conclusion, and checks that the record has 6 checks, all PASS. Output: RESULT checks of the record ks-source-conditions.json = 6 of 6 PASS, the record's conclusion (no recorded Kohn-Sham state is an admissible source; C1 and C2 fail for every nonzero state, C2 also after integration over x_0; the history is a prescribed background without back-reaction), and the first PASS line.

In [3], the Lovelock components of the record as sympy expressions.

```
equations = read_json(EQUATIONS)
ad1, ad2 = sp.symbols("ad1 ad2", real=True)  # a4' and a4'' (the record's names)
H = sp.symbols("H", positive=True)  # the constant H of the metric
NAMES = {"ad1": ad1, "ad2": ad2, "H": H}  # how the record's names become symbols
```

The record of the a_4 equations is read. `sp.symbols` makes sympy **symbols**, letters that sympy computes with exactly: `ad1` and `ad2` stand for a_4' and a_4'' and are declared real numbers; `H` is declared positive. `NAMES` tells sympy which symbol each name of the record means.

```
def parse(text):
    """A formula of the record (Wolfram Language text) as a sympy expression."""
    return sp.sympify(text.replace("^", "**"), locals=NAMES)
```

The record stores its formulas as text in the Wolfram Language, where a power is written `^`; Python writes `**`. `parse` replaces the one by the other and lets `sp.sympify` read the text as a sympy expression, with the names of `NAMES`.

```
COMPONENTS = ("x1x1", "x4x4", "x5x5", "x0x0", "x4x0")
E = {k: {c: parse(equations["lovelockTensors"][f"E{k}"][c]["input"])
         for c in COMPONENTS}
     for k in (1, 2, 3)}  # E[k][component]: the Lovelock tensor of order k
for c in COMPONENTS:
    say(f"E_(1)^{c[:2]}_{c[2:]} = {E[1][c]}")
```

`COMPONENTS` is a **tuple** (a fixed list in round brackets) of the five components needed. The next line is a **dictionary comprehension** inside another: for each order $k = 1, 2, 3$ and each component `c`

it reads the record's text `equations["lovelockTensors"]["E1"]["x1x1"]["input"]` (and so on) and parses it. `E[2]["x5x5"]` is then $E_{(2)}{}^{x_5}{}_{x_5}$. The loop prints the five components of Einstein's tensor; `c[:2]` is the first two characters of the name (`x1`) and `c[2:]` the rest. Output: `E_(1)^x1_x1 = 15*H**2 - 3*ad1**2 + ad2`, `E_(1)^x4_x4 = 21*H**2 + 3*ad1**2`, `E_(1)^x5_x5 = 15*H**2 - 3*ad1**2 - ad2`, `E_(1)^x0_x0 = 15*H**2 - 3*ad1**2` and `E_(1)^x4_x0 = 0`, the Einstein components of Section 17.3.

In [4], the three conditions on the left-hand sides.

```
allowed = {ad1, ad2, H}  # the only symbols a left-hand side may contain
no_x0 = all(E[k][c].free_symbols <= allowed for k in E for c in COMPONENTS)
reproduces(no_x0 and all(E[k]["x4x0"] == 0 for k in E),
           "C1: the left-hand sides are free of x0 and the x4-x0 one is 0",
           WL_A4, ["P1_structure", "P2_structure", "P3_structure"])
```

`{ad1, ad2, H}` is a **set**, a collection without order. `.free_symbols` is the set of symbols that an expression contains, and `<=` between sets means "is contained in". So `no_x0` is true when no component of any order contains anything but a_4', a_4'' and H. (A dependence on x_0 would have to appear as a symbol such as `x0` or `cc`.) Together with "every x_4x_0 component is zero" this is the left-hand side of C1 (Section 17.4); the check also requires the three structure checks of the Wolfram report to be PASS.

```
identity = [sp.expand(E[k]["x1x1"] + E[k]["x5x5"] - 2 * E[k]["x0x0"]) for k in E]
say(f"E^x1_x1 + E^x5_x5 - 2 E^x0_x0 for k = 1, 2, 3: {identity}")
reproduces(all(value == 0 for value in identity),
           "C2: E^x1_x1 + E^x5_x5 = 2 E^x0_x0 for every order k",
           WL_A4, ["algebraic_identity_x1_plus_x5_minus_2x0"])
```

For each order, `sp.expand` multiplies out $E^{x_1}{}_{x_1} + E^{x_5}{}_{x_5} - 2E^{x_0}{}_{x_0}$ and collects equal terms. The printed list is `[0, 0, 0]`: the identity behind C2 (Section 17.5) holds for each order separately.

```
linear = {ad2: 0}  # the linear member: a4'' = 0 (and a4' = A H, a constant)
equal = all(sp.expand((E[k]["x1x1"] - E[k]["x0x0"]).subs(linear)) == 0
            and sp.expand((E[k]["x5x5"] - E[k]["x0x0"]).subs(linear)) == 0
            for k in E)
rho_side = all(E[k]["x4x4"].free_symbols <= {ad1, H} for k in E)
reproduces(equal and rho_side,
           "C3: for a4'' = 0 the pressures are equal and rho is constant",
           PY_A4, ["linear_member_equal_pressures"])
```

`.subs(linear)` replaces a_4'' by 0. Then `equal` is true when, for every order, the x_1 and x_5 components both equal the x_0 component; so the three pressure equations have the same left-hand side and give $p_3 = p_t = p_0$. `rho_side` is true when the x_4 components contain only a_4' and H; with $a_4' = AH$ constant the constraint then gives a constant ρ. That is C3 (Section 17.6), reproduced from the sympy report. Output: three PASS lines, each followed by the record it reproduces.

In [5], the recorded Kohn-Sham states.

```
COLUMNS = ("rho", "p3", "p_t", "p0")  # the four diagonal components of the source
```

```
def read_profile(path):
    """A profile table as a dictionary: column name -> numpy array (151 values)."""
    data = np.genfromtxt(path, delimiter=",", names=True)
    return {name: data[name] for name in data.dtype.names}
```

`COLUMNS` names the four columns of a profile file that hold the source. `np.genfromtxt` reads a table of numbers from a text file; `delimiter=","` says that commas separate the entries, and `names=True` that the first line holds the column names. `data.dtype.names` lists them, and the function returns a dictionary from each name to its column, an array of 151 numbers.

```
files = sorted(repository_file(f"{GROUND}/profiles").glob("*.csv"),
               key=lambda path: path.name)  # in alphabetical order, as the record
profiles = {path.stem: read_profile(path) for path in files}
```

`.glob("*.csv")` finds every file whose name ends in `.csv` in the folder of profiles; `sorted(..., key=lambda path: path.name)` puts them in alphabetical order of their names (a `lambda` is a one-line function without a name; here it returns the file name). `path.stem` is the file name without `.csv`, the name of the state, such as `N136_lam0_a10`. So `profiles["N136_lam0_a10"]["p0"]` is the hidden pressure of that state at the 151 points.

```
with repository_file(f"{GROUND}/emt-integrals.csv").open(
        encoding="utf-8", newline="") as handle:
    integrals = {row["id"]: row for row in csv.DictReader(handle)}
physics = read_json("Revision/kohn_sham/results/parameters.json")["physics"]
```

`with ... as handle:` opens the table of integrals and closes it again at the end of the indented block. `csv.DictReader` reads it row by row, each row as a dictionary from the column name to the entry (as text); `integrals` maps the state name in the column `id` to its row. `physics` is the part of the solver's parameter record with H, the tip cutoff and Vol_7.

```
scale = {sid: float(max(np.max(np.abs(prof[c])) for c in COLUMNS))
         for sid, prof in profiles.items()}  # max|T| of every state
zero = [sid for sid in profiles if scale[sid] == 0.0]  # T = 0 everywhere
nonzero = [sid for sid in profiles if scale[sid] > 0.0]
```

For each state (`sid`, the state's name, and `prof`, its profile), `np.abs` takes absolute values entry by entry, `np.max` the largest of a column, and `max(...)` the largest of the four columns: this is max|T|. A **list comprehension** `[sid for sid in profiles if ...]` collects the names that satisfy a condition: `zero` holds the states whose tensor vanishes everywhere, `nonzero` the others.

```
y = profiles["N136_lam0_a10"]["y"]  # the grid of the hidden coordinate
same_grid = all(np.array_equal(prof["y"], y) for prof in profiles.values())
report("states read", len(profiles))
report("states with a nonzero tensor", len(nonzero))
report("grid of y", f"{len(y)} points from {y[0]:g} to {y[-1] + 0.0:g}, "
       f"step {y[1] - y[0]:.2f}")
```

`y` is the column of grid points of one state; `np.array_equal` checks that every state uses exactly the same points. `y[0]` is the first point and `y[-1]` the last (a negative index counts from the end). The last point is stored as -0 (a zero with a minus sign, which a computer can hold); adding `0.0` turns it into $+0$, so that it prints as 0. The format `:g` writes a number in its shortest form and `:.2f` with two decimals.

```
H_value, L_cut, VOL7 = physics["H"], physics["L_tipCutoff"], physics["Vol7"]
report("H, tip cutoff L, Vol_7", f"{H_value:g}, {L_cut:g}, {VOL7:.6g}")
say("ks-theory.json, emt.offDiagonal: "
    + read_json("Revision/kohn_sham/ks-theory.json")["emt"]["offDiagonal"])
check(len(profiles) == 75 and len(nonzero) == 70 and len(zero) == 5 and same_grid
      and sorted(integrals) == sorted(profiles),
      "75 states on one grid (70 nonzero, 5 zero); every state has its integrals")
```

The three numbers of the run are read and printed; `:.6g` keeps six significant digits. The cell prints the Kohn-Sham theory record's statement on the mixed component, and checks the counts, the common grid, and that the table of integrals has exactly the same states (`sorted` of a dictionary is the sorted list of its keys). Output: 75 states, 70 with a nonzero tensor, 151 points from -3 to 0 with step 0.02; $H = 1$, $L = 3$, $\mathrm{Vol}_7 = 15875.2$; the statement that ${T^{x_4}}_y = 0$ for eigen-orbitals; and a PASS line.

In [6], the hidden coordinate and the energy profiles (figure 1).

```
SLICES = {"a00": 0.0, "a05": 0.5, "a10": 1.0, "a15": 1.5, "a20": 2.0}  # a4,0
SHADES = ["#86b6ef", "#5598e7", "#2a78d6", "#1c5cab", "#104281"]  # light -> dark
history136 = [f"N136_lam0_{tag}" for tag in SLICES]  # N = 136, lambda = 0
```

`SLICES` maps the slice tag of a state name to the value $a_{4,0}$. `SHADES` are five colours from light to dark blue, written as **hexadecimal colour codes** (two digits each for red, green and blue). `history136` lists the five states with $N = 136$, $\lambda = 0$; a loop over a dictionary visits its keys in the order they were written.

```
falls = [float(np.max(profiles[s]["rho"]) / np.min(profiles[s]["rho"]))
         for s in history136]  # how much rho changes along y, slice by slice
check(all(float(np.min(profiles[s]["rho"])) > 0.0 for s in history136),
      "N = 136, lambda = 0: rho is positive at every point of every slice")
```

For each of the five states, `falls` holds the ratio of the largest to the smallest value of ρ along y. The check confirms that ρ is positive everywhere for these states, which a logarithmic axis needs (the logarithm of zero or of a negative number does not exist). Output: the PASS line.

```
z = np.logspace(-9, np.log10(np.pi / 2), 400)  # z from 1e-9 to pi/2
z_tip = float(np.arcsin(np.exp(-18.0)))  # where y = -3 (6 H y = -18 with H = 1)
```

`np.logspace(a, b, 400)` gives 400 numbers from 10^a to 10^b, equally spaced on a logarithmic scale: here from 10^{-9} to $\pi/2$. The tip cutoff $y = -3$ sits where $\sin z = e^{6Hy} = e^{-18}$, that is $z = \arcsin(e^{-18})$, about 1.5×10^{-8}.

```
fig, (left, right) = plt.subplots(1, 2, figsize=(9.0, 3.8))
left.plot(z, np.log(np.sin(z)) / 6.0, color="#2a78d6", lw=2.0)
left.axvspan(z_tip, np.pi / 2, color="#1baf7a", alpha=0.15,
             label="computed patch, $-3 \\leq y \\leq 0$")
left.axhline(-3.0, color="0.4", ls="--", lw=1.0)
left.set_xscale("log")
left.set_xlabel("$z = 6Hx_0$ (logarithmic axis)")
left.set_ylabel("hidden coordinate $y$ (units of $1/H$)")
left.set_title("$y = \\ln(\\sin z)/(6H)$, $H = 1$")
left.legend(loc="lower right", fontsize=8)
```

`plt.subplots(1, 2, ...)` makes a figure with one row of two panels (called **axes** in matplotlib), 9.0 by 3.8 inches; the two panels are named `left` and `right`. The left panel draws $y = \ln(\sin z)/6$ (with $H = 1$) against z; `lw` is the line width. `axvspan` shades the vertical band from the tip cutoff to $\pi/2$, the computed patch, with 15 per cent opacity; `axhline` draws a dashed grey horizontal line (the line style `ls` given as two hyphens) at $y = -3$. `set_xscale("log")` makes the horizontal axis logarithmic. The labels and the title are written with `$...$`, which matplotlib prints as mathematics (a backslash is written twice inside a Python string). `legend` shows the label of the shaded band.

```
for shade, sid, a40 in zip(SHADES, history136, SLICES.values()):
    right.plot(y, profiles[sid]["rho"] / scale[sid], color=shade, lw=1.8,
               label=f"$a_{{4,0}} = {a40:g}$")
right.axhline(1e-3, color="0.4", ls=":", lw=1.2,
              label="admissible: constant (example)")
right.set_yscale("log")
right.set_xlabel("hidden coordinate $y$ (tip $-3$, brane $0$)")
right.set_ylabel("$\\rho(y)$ / max|T|")
right.set_title("$N = 136$, $\\lambda = 0$")
right.legend(fontsize=7, loc="upper right")
fig.tight_layout()
```

`zip` walks through three lists side by side: a colour, a state name and its slice value. Each pass draws $\rho(y)$ divided by max|T| of the state. A dotted line (`ls=":"`) at 10^{-3} shows, as an example, what an admissible profile looks like: a constant. `set_yscale("log")` makes the vertical axis logarithmic. `fig.tight_layout()` arranges the panels so that their labels do not overlap.

```
save_figure(fig, "rho_profiles",
            "Left: the hidden coordinate $y = \\ln(\\sin z)/(6H)$ against $z = 6Hx_0$ "
            "(logarithmic axis, $H = 1$); the shaded band is the computed patch from "
            "the tip cutoff $y = -3$ to the brane $y = 0$, which covers $z$ from "
            f"${z_tip / 1e-8:.1f} \\times 10^{{-8}}$ to $\\pi/2$. Right: the energy "
            "density $\\rho(y)$ of the Kohn-Sham state $N = 136$, $\\lambda = 0$ "
            "divided by the largest component of the state, at the five slices "
            "$a_{4,0} = 0$ to $2$ (logarithmic vertical axis). The largest value of "
            f"$\\rho$ is {min(falls):.0f} to ${tex_number(max(falls))}$ times its "
            "smallest "
            "value, depending on the slice, while condition C1 of the field "
            "equations demands a horizontal line such as the dotted one.")
```

`save_figure` saves the figure and records the caption. The caption is written as twelve strings next to each other, one per line inside the round brackets; Python joins strings written next to each other

into one string, so the twelve lines make one caption. Most of them are plain strings. Two start with `f` and contain computed numbers in braces: `z_tip / 1e-8` written with one decimal (`:.1f`) gives 1.5, so the text reads 1.5×10^{-8} (the doubled braces `{{-8}}` print one pair of braces, which the book's mathematics needs); `min(falls)` with no decimals (`:.0f`) gives 319, and `tex_numb er(max(falls))` gives 1.1×10^{5}. The backslashes are doubled because a single backslash in a Python string starts a special character. Output: figure 17a.1 and the line Figure 17a.1 saved as Revision/textbook/figures/17a_1_rho_profiles.png.

What figure 17a.1 shows. Left: the curve $y(z)$ is a straight line on the logarithmic z axis, because $y = \ln(\sin z)/6 \approx \ln(z)/6$ for small z; the shaded patch $-3 \le y \le 0$ covers z from 1.5×10^{-8} to $\pi/2$, almost the whole hidden direction. Right: the energy density of the five states $N = 136$, $\lambda = 0$ on a logarithmic axis. Near the tip it is about a tenth of max|T|; toward the brane it falls by two to five powers of ten, the more the later the slice (the largest value is 319 to 1.1×10^{5} times the smallest). Condition C1 demands a horizontal line such as the dotted example. The student should see at a glance that C1 fails, and by a huge margin.

In [7], condition C1 measured.

```
TOL = 1e-6  # the relative tolerance of the record
spread = {sid: float(np.max(profiles[sid]["rho"]) - np.min(profiles[sid]["rho"]))
          / scale[sid] for sid in nonzero}
smallest = min(spread, key=spread.get)  # the state that depends least on x0
largest = max(spread, key=spread.get)  # the state that depends most on x0
report("smallest spread of rho / max|T|", f"{spread[smallest]:.6g} ({smallest})")
report("largest spread of rho / max|T|", f"{spread[largest]:.6g} ({largest})")
```

`TOL` is the record's tolerance. `spread` holds, for each of the 70 nonzero states, the spread of ρ divided by max|T| (Section 17.4). `min(spread, key=spread.get)` returns the name whose value is smallest (`spread.get` looks a value up by its name), and `max` the largest. Output: the smallest spread is 0.0497329 (state `N136_lamm2_a20`), the largest 0.995037 (`N8_lamm1_a00`).

```
detail = record_entry(SOURCE_REPORT, "ks_profiles_depend_on_x0")["detail"]
text = f">= {spread[smallest]:.6g} (smallest: {smallest})"  # as the record prints it
reproduces(all(value > TOL for value in spread.values()) and text in detail
           and "75 ground-state profiles" in detail
           and "70 with a nonzero" in detail,
           "C1 fails: every nonzero state depends on x0",
           SOURCE_REPORT, ["ks_profiles_depend_on_x0"])
```

`detail` is the record's text for its check `ks_profiles_depend_on_x0`. `text` is our smallest value written exactly as the record writes it; `text in detail` is true when the record contains this text. The check passes when every spread exceeds the tolerance and the record states our numbers and counts. Output: PASS C1 fails: every nonzero state depends on x0, reproducing the record's check. (COMPUTED; the smallest spread, 0.0497, is fifty thousand times the tolerance.)

In [8], the map of C1 (figure 2).

```
from matplotlib.colors import LogNorm  # a logarithmic colour scale
```

```
TAGS = [("m2", "-\\lambda_2"), ("m1", "-\\lambda_1"), ("0", "0"),
        ("p1", "+\\lambda_1"), ("p2", "+\\lambda_2")]  # the couplings, in order
ROWS = [(n, tag, label) for n in (8, 136, 688) for tag, label in TAGS]
```

`LogNorm` turns values into colours on a logarithmic scale. `TAGS` pairs each coupling tag of the state names with its mathematical label. `ROWS` lists the 15 rows of the map: each particle number with each coupling.

```
def describe(sid):
    """The state name N136_lamm2_a20 written as N = 136, lambda = -lambda_2, ..."""
    n, lam, slice_tag = sid.split("_")
    label = dict(TAGS)[lam[3:]]  # lam[3:] is m2, m1, 0, p1 or p2
    return (f"$N = {n[1:]}$, $\\lambda = {label}$, "
            f"$a_{{4,0}} = {SLICES[slice_tag]:g}$")
```

`describe` turns a state name into mathematics for a caption. `sid.split("_")` cuts `N136_lamm2_a20` at the underscores into `N136`, `lamm2` and `a20`. `n[1:]` drops the letter N; `lam[3:]` drops `lam` and leaves `m2`; `dict(TAGS)` turns the list of pairs into a dictionary, which gives $-\lambda_2$; `SLICES["a20"]` is 2.0, printed as 2.

```
def state_table(values):
    """A 15 x 5 array of values[state] (NaN for the states with T = 0)."""
    table = np.full((len(ROWS), len(SLICES)), np.nan)
    for i, (n, tag, _) in enumerate(ROWS):
        for j, slice_tag in enumerate(SLICES):
            sid = f"N{n}_lam{tag}_{slice_tag}"
            if sid in values:
                table[i, j] = values[sid]
    return table
```

`state_table` arranges a value per state into a table of 15 rows and 5 columns. `np.full(shape, n p.nan)` starts with every entry equal to NaN ("not a number", the computer's mark for a missing value). `enumerate` counts the rows $i = 0, 1, \ldots$ while it walks through them; `_` is a name for a part we do not need. The state name is rebuilt from the row and column, and its value is entered if it exists; the five states with $T = 0$ stay NaN.

```
def draw_table(ax, table, norm, fmt):
    """Draw a state table as a heat map with the value written in every cell."""
    cmap = plt.get_cmap("viridis").copy()
    cmap.set_bad("#d9d9d9")  # grey for NaN (the states with T = 0)
    image = ax.imshow(np.ma.masked_invalid(table), cmap=cmap, norm=norm,
                      aspect="auto")
```

`draw_table` draws such a table as a heat map. `viridis` is a colour scale from dark purple through blue and green to yellow; `.copy()` makes a private copy, and `set_bad` colours missing entries grey. `np.ma.masked_invalid` marks the NaN entries as missing; `ax.imshow` draws the table as coloured squares with the given colour scale `norm`; `aspect="auto"` lets the squares stretch to fill the panel.

```
    for i in range(table.shape[0]):
        for j in range(table.shape[1]):
            value = table[i, j]
            if np.isnan(value):
                ax.text(j, i, "T = 0", ha="center", va="center", fontsize=7)
                continue
            light = norm(value) > 0.6  # yellow-green cells: black text reads best
            ax.text(j, i, format(value, fmt), ha="center", va="center", fontsize=7,
                    color="black" if light else "white")
```

Two loops visit every square (`table.shape[0]` is the number of rows, `table.shape[1]` of columns). A missing entry is labelled `T = 0` and `continue` jumps to the next square. Otherwise the value is written in the middle of its square (`ha` and `va` are the horizontal and vertical alignment) with the format `fmt`; `norm(value)` is the position of the value on the colour scale between 0 and 1, and on the light upper part the text is black, elsewhere white.

```
    ax.set_xticks(range(len(SLICES)), [f"{a:g}" for a in SLICES.values()])
    ax.set_yticks(range(len(ROWS)),
                  [f"$N = {n}$, $\\lambda = {label}$" for n, _, label in ROWS],
                  fontsize=7)
    ax.set_xlabel("slice $a_{4,0}$")
    ax.grid(False)
    return image
```

The column marks are labelled with the slice values and the row marks with N and λ; the grid of the default settings is switched off over the heat map; the drawn image is returned, so that a colour bar can be attached to it.

```
n8_spread = [value for sid, value in spread.items() if sid.startswith("N8_")]
low8, high8 = f"{min(n8_spread):.3f}", f"{max(n8_spread):.3f}"  # three decimals
n8_text = (f"all have the spread ${low8}$" if low8 == high8  # equal when rounded
           else f"have spreads of ${low8}$ to ${high8}$")
```

The spreads of the 20 nonzero $N = 8$ states are collected; their smallest and largest are written with three decimals. If the two texts agree, the caption says that all have the same spread; otherwise it gives the range. (This is a conditional expression, `a if condition else b`.)

```
fig, ax = plt.subplots(figsize=(6.4, 6.0))
image = draw_table(ax, state_table(spread), LogNorm(0.04, 1.0), ".3f")
fig.colorbar(image, ax=ax, label="spread of $\\rho$ / max|T| (C1 needs 0)")
ax.set_title("Condition C1: dependence on the hidden direction")
```

A single panel; the spread table is drawn with a logarithmic colour scale from 0.04 to 1 and three decimals in each square; a **colour bar** beside it translates colours into values; the title names the condition.

```
save_figure(fig, "c1_map",
            "The spread $(\\max_y \\rho - \\min_y \\rho)/\\max|T|$ of the energy "
```

```
            "density along the hidden coordinate for all 75 recorded Kohn-Sham "
            "ground states: rows are the particle numbers $N = 8, 136, 688$ with "
            "the five couplings, columns the slices $a_{4,0}$ (logarithmic colour "
            "scale, pure numbers). "
            "Condition C1 needs $0$ in every cell; the smallest value is "
            f"${spread[smallest]:.4f}$ ({describe(smallest)}), and the $N = 8$ "
            f"states, made of brane zero modes, {n8_text}, almost the whole "
            "size of the tensor. Grey cells: the five states with no source at all.")
```

The caption, joined from its strings as in In [6], inserts three computed pieces: the smallest spread with four decimals (`:.4f`), 0.0497; the state written by `describe`, ($N = 136$, $\lambda = -\lambda_2$, $a_{4,0} = 2$); and the $N = 8$ text, "all have the spread 0.995". Output: figure 17a.2 and its saved line.

What figure 17a.2 shows. Rows: $N = 8, 136, 688$, each with the couplings $-\lambda_2$ to $+\lambda_2$; columns: the five slices; colour and number: the spread of ρ divided by max|T| (a pure number). C1 needs 0 in every square. The $N = 8$ rows are yellow, 0.995 everywhere: their energy density varies by almost the whole size of their tensor. The $N = 136$ and $N = 688$ rows lie between 0.05 and 0.42, largest at the first slice. The grey row, $N = 8$ with $\lambda = 0$, has no source at all. No square is close to 0.

In [9], condition C2 point by point.

```
violation = {sid: profiles[sid]["p3"] + profiles[sid]["p_t"]
             - 2.0 * profiles[sid]["p0"] for sid in nonzero}  # V(y)
size = {sid: float(np.max(np.abs(violation[sid]))) / scale[sid] for sid in nonzero}
low = min(size, key=size.get)  # the state closest to C2
high = max(size, key=size.get)  # the state farthest from C2
report("smallest max|V| / max|T|", f"{size[low]:.6g} ({low})")
report("largest max|V| / max|T|", f"{size[high]:.6g} ({high})")
```

For each nonzero state, `violation` is the array $V(y) = p_3 + p_t - 2p_0$ at the 151 points (numpy adds and multiplies arrays entry by entry), and `size` its largest absolute value divided by max|T|. Output: the smallest size is 2.09192 (`N136_lamp2_a20`) and the largest 3.99006 (`N8_lamm1_a00`).

```
detail = record_entry(SOURCE_REPORT, "ks_profiles_violate_algebraic_condition")[
    "detail"]
text = f"between {size[low]:.6g} ({low}) and {size[high]:.6g} ({high})"
reproduces(all(value > TOL for value in size.values()) and text in detail,
           "C2 fails point by point for every nonzero state",
           SOURCE_REPORT, ["ks_profiles_violate_algebraic_condition"])
```

As in In [7]: the record's text must contain our two numbers and states exactly. Output: PASS C2 fails point by point for every nonzero state, reproducing the record's check. (COMPUTED.) A violation of 2 to 4 times the largest component is not a small error: the two sides of C2 are not even of the same size.

In [10], the violation profiles (figure 3).

```
plotted = [f"N{n}_lam0_{tag}" for n in (136, 688) for tag in SLICES]
signs = {sid: np.sign(violation[sid]) for sid in plotted}  # +1, -1 (or 0)
changes = {sid: int(np.sum(signs[sid][1:] * signs[sid][:-1] < 0)) for sid in plotted}
```

`plotted` lists the ten states with $\lambda = 0$ and $N = 136$ or 688. `np.sign` gives $+1$, -1 or 0 for each entry. `signs[sid][1:]` is the array without its first entry and `signs[sid][:-1]` without its last, so their product, entry by entry, is the product of the signs of neighbouring points; it is negative exactly where V changes sign between two neighbours. `np.sum(... < 0)` counts these places (true counts as 1).

```
at_tip = [abs(float(violation[sid][0])) / scale[sid] for sid in plotted]
at_brane = [abs(float(violation[sid][-1])) / scale[sid] for sid in plotted]
say(f"sign changes of the ten plotted profiles: {sorted(set(changes.values()))}")
check(all(count == 1 for count in changes.values())
      and min(at_brane) > 0.0,
      "each plotted V(y) changes sign exactly once and is nonzero at the brane")
```

`at_tip` and `at_brane` hold $|V|/\max|T|$ at the first point ($y = -3$) and at the last ($y = 0$). `set(...)` keeps each different count once, and `sorted` puts them in order. Output: `sign changes of the ten plotted profiles: [1]`, and a PASS line: every plotted profile changes sign exactly once and is not zero at the brane.

```
fig, axes = plt.subplots(1, 2, figsize=(9.0, 3.8), sharey=True)
for ax, n in zip(axes, (136, 688)):
    for shade, (tag, a40) in zip(SHADES, SLICES.items()):
        sid = f"N{n}_lam0_{tag}"
        ax.plot(y, violation[sid] / scale[sid], color=shade, lw=1.8,
                label=f"$a_{{4,0}} = {a40:g}$")
    ax.axhline(0.0, color="#e34948", ls="--", lw=1.2, label="C2: $V = 0$")
    ax.set_yscale("symlog", linthresh=1e-7)
    ax.set_yticks([-1e-1, -1e-3, -1e-5, -1e-7, 0.0, 1e-7, 1e-5, 1e-3, 1e-1, 1e1])
    ax.set_xlabel("hidden coordinate $y$")
    ax.set_title(f"$N = {n}$, $\\lambda = 0$")
axes[0].set_ylabel("$V = p_3 + p_t - 2p_0$, divided by max|T|")
axes[1].legend(fontsize=7, loc="upper right")
fig.tight_layout()
```

Two panels that share their vertical axis (`sharey=True`), one per particle number. In each, the five violation profiles divided by max|T| are drawn in the five shades, and a red dashed line marks $V = 0$, the value C2 demands. `set_yscale("symlog", linthresh=1e-7)` makes the vertical axis symmetric logarithmic: linear between -10^{-7} and 10^{-7}, logarithmic beyond, in both directions. `set_yticks` chooses the marks. `axes[0]` is the left panel and `axes[1]` the right one.

```
save_figure(fig, "violation_profiles",
            "The violation profiles $V(y) = p_3 + p_t - 2p_0$ of the Kohn-Sham ground "
            "states with $\\lambda = 0$, divided by the largest component of each "
            "state, for $N = 136$ (left) and $N = 688$ (right) at the five slices "
            "$a_{4,0}$ (horizontal axis: the hidden coordinate $y$; vertical axis "
            "symmetric logarithmic, linear between $-10^{-7}$ and $10^{-7}$). "
            "Condition C2 of the field equations demands the dashed line $V = 0$; "
            f"instead $|V|$ is {min(at_tip):.2f} to {max(at_tip):.2f} times max|T| "
            "at the tip, every profile changes sign exactly once, and at the brane "
            f"$|V|$/max|T| is still between ${tex_number(min(at_brane))}$ and "
            f"${tex_number(max(at_brane))}$, small but not zero.")
```

The caption, joined from its strings as in In [6], inserts the range of $|V|/\max|T|$ at the tip with two decimals, 2.36 to 2.37, and at the brane in powers of ten, 7.1×10^{-7} to 4.0×10^{-3}. Output: figure 17a.3 and its saved line.

What figure 17a.3 shows. Horizontal axis: y from the tip cutoff to the brane (units of $1/H$); vertical axis: $V/\max|T|$, a pure number, on the symmetric logarithmic scale. Every profile starts at the tip with V about 2.4 times max|T| and positive, drops steeply through zero once, near $y \approx -2.2$ (for the first slice at $y \approx -2.05$ when $N = 136$ and $y \approx -1.75$ when $N = 688$), stays negative, and rises toward zero at the brane without reaching it. C2 demands the red dashed line. Section 17.14 will explain the single change of sign: V is the slope of p_0, and p_0 has one maximum.

In [11], the map of C2 (figure 4).

```
from matplotlib.colors import Normalize  # a linear colour scale

fig, ax = plt.subplots(figsize=(6.4, 6.0))
image = draw_table(ax, state_table(size), Normalize(2.0, 4.0), ".3f")
fig.colorbar(image, ax=ax, label="max$|p_3 + p_t - 2p_0|$ / max|T| (C2 needs 0)")
ax.set_title("Condition C2: $p_3 + p_t = 2p_0$ point by point")
save_figure(fig, "c2_map",
            "The size $\\max_y|p_3 + p_t - 2p_0|/\\max|T|$ of the violation of "
            "condition C2 for all 75 recorded Kohn-Sham ground states (rows: particle "
            "number and coupling; columns: the slice $a_{4,0}$; linear colour scale, "
            "pure numbers). C2 needs $0$; every nonzero state violates it by "
            f"${size[low]:.2f}$ to ${size[high]:.2f}$ times its largest component. "
            "The $N = 8$ states, made of brane zero modes, have the same value at "
            "every slice; grey cells: no source.")
```

`Normalize` is imported first (a `from ... import` line may stand anywhere in a cell). The same heat map as In [8], now of `size` with a linear colour scale (`Normalize`) from 2 to 4, with its colour bar and title; the caption, joined from its strings as in In [6], inserts the range with two decimals, 2.09 to 3.99. Output: figure 17a.4 and its saved line.

What figure 17a.4 shows. The same rows and columns as figure 17a.2; colour and number: $\max_y |V|/\max|T|$, a pure number. C2 needs 0. The $N = 8$ rows show 3.990 in every square (the same state at every slice, In [18]); the $N = 136$ and $N = 688$ rows lie between 2.09 and 2.50. Every nonzero state violates C2 by more than twice its own largest component.

In [12], a worked example: three points of one state.

```
example = profiles["N136_lam0_a10"]
POINTS = (-3.0, -1.5, 0.0)  # tip, middle, brane
detail = record_entry(SOURCE_REPORT, "ks_profiles_violate_algebraic_condition")[
    "detail"]
rows = []
```

The state $N = 136$, $\lambda = 0$, $a_{4,0} = 1$, which the record uses as its example; the three values of y the record quotes; the record's text; and an empty list for the results.

```
for target in POINTS:
    i = int(np.argmin(np.abs(example["y"] - target)))  # nearest grid point
```

```
    values = {c: float(example[c][i]) for c in ("y",) + COLUMNS}
    values["V"] = values["p3"] + values["p_t"] - 2.0 * values["p0"]
    rows.append(values)
    text = ("y = {y:.6g}: rho = {rho:.6g}, p3 = {p3:.6g}, p_t = {p_t:.6g}, "
            "p0 = {p0:.6g}, p3 + p_t - 2 p0 = {V:.6g}").format(**values)
    say(text)
    values["in_record"] = text in detail  # the record prints the same text?
```

For each target value of y: `np.abs(example["y"] - target)` is the distance of every grid point from it, and `np.argmin` the position of the smallest distance, the nearest grid point i. `values` collects y, ρ, p_3, p_t, p_0 there (`("y",) + COLUMNS` joins two tuples) and V. `"...".format(**values)` fills the named places `{y:.6g}` and so on from the dictionary, with six significant digits as the record prints them. The line is printed, and `in_record` notes whether the record contains exactly this text.

```
reproduces(all(r["in_record"] for r in rows) and all(r["V"] != 0 for r in rows),
           "the three example points of N136_lam0_a10 equal the record",
           SOURCE_REPORT, ["ks_profiles_violate_algebraic_condition"])
```

The check passes when the record contains all three lines and $V \neq 0$ at all three points. Output:

point	ρ	p_3	p_t	p_0	$V = p_3 + p_t - 2p_0$
tip, $y = -3$	43.0702	158.268	-0	-431.733	1021.73
middle, $y = -1.5$	0.707818	0.498835	0	0.643324	-0.787813
brane, $y = -0$	0.00211576	0.000391237	-0	0.000942049	-0.00149286

(units of m^8), and the PASS line. A printed -0 is a zero stored with a minus sign; it equals 0. Check one line by hand: at the tip $V = 158.268 + 0 - 2 \times (-431.733) = 158.268 + 863.466 = 1021.734$, which rounds to the printed 1021.73. (COMPUTED; the record's check `ks_profiles_violate_algebraic_condition` prints the same three lines.)

In [13], the two sides of C2 as bars (figure 5).

```
fig, axes = plt.subplots(1, 3, figsize=(9.0, 3.4))
for ax, values, where in zip(axes, rows, ("tip", "middle", "brane")):
    sides = [values["p3"] + values["p_t"], 2.0 * values["p0"]]
    bars = ax.bar(["$p_3 + p_t$", "$2p_0$"], sides, color=["#2a78d6", "#eb6834"])
```

Three panels, one per point. In each, `sides` holds the two sides of C2, and `ax.bar` draws them as a blue and an orange bar with mathematical labels under them; `bars` keeps the two drawn bars.

```
    for bar, value in zip(bars, sides):
        ax.annotate(f"{value:.4g}", (bar.get_x() + bar.get_width() / 2, value),
                    ha="center", va="bottom" if value >= 0 else "top", fontsize=8)
    ax.axhline(0.0, color="0.3", lw=0.8)
    y_here = values["y"] + 0.0  # + 0.0 turns -0 into 0
    ax.set_title(f"{where}: $y = {y_here:g}$", fontsize=10)
    ax.margins(y=0.18)
```

`ax.annotate` writes the value of each bar, with four significant digits, at the middle of the bar's top (`bar.get_x()` is its left edge and `bar.get_width()` its width), above a positive bar and below a negative one. A thin line marks zero; the title names the point; `margins(y=0.18)` leaves 18 per cent of free space above and below, so that the numbers fit.

```
axes[0].set_ylabel("pressure (units of $m^8$)")
fig.suptitle("$N = 136$, $\\lambda = 0$, $a_{4,0} = 1$: the two sides of C2")
fig.tight_layout()
tip, middle, brane = rows
factors = [2.0 * r["p0"] / (r["p3"] + r["p_t"]) for r in (middle, brane)]
tip_left, tip_right = tip["p3"] + tip["p_t"], 2.0 * tip["p0"]  # the two sides
```

`suptitle` writes a title over the whole figure. `tip, middle, brane = rows` gives the three dictionaries names. `factors` holds $2p_0/(p_3+p_t)$ at the middle and at the brane, and `tip_left`, `tip_righ t` the two sides at the tip.

```
save_figure(fig, "three_points",
            "The two sides of condition C2, $p_3 + p_t$ (blue) and $2p_0$ (orange), "
            "of the Kohn-Sham state $N = 136$, $\\lambda = 0$, $a_{4,0} = 1$ at the "
            "tip $y = -3$, in the middle $y = -1.5$ and at the brane $y = 0$ "
            "(vertical axes: proper pressure in units of $m^8$, each panel with its "
            "own scale). C2 demands equal bars; near the tip the two sides even have "
            f"opposite signs (${tip_left:.1f}$ against "
            f"${tip_right:.1f}$), in the middle $2p_0$ is {factors[0]:.2f} "
            f"times $p_3 + p_t$ and at the brane {factors[1]:.2f} times.")
```

The caption, joined from its strings as in In [6], inserts the two sides at the tip with one decimal, 158.3 against −863.5, and the two factors with two decimals, 2.58 and 4.82. Output: figure 17a.5 and its saved line.

What figure 17a.5 shows. Three panels for the tip, the middle and the brane of the state $N = 136$, $\lambda = 0$, $a_{4,0} = 1$; vertical axes: pressure in units of m^8, each with its own scale. C2 demands two bars of equal height in each panel. At the tip the two sides do not even have the same sign; in the middle $2p_0$ is 2.58 times $p_3 + p_t$ (since $1.286648/0.498835 = 2.579$); at the brane it is 4.82 times. Exercise 2 repeats this arithmetic.

In [14], condition C2 after integration over x0.

```
def integral(sid, column):
    """The integral 2 Vol_7 int e^{6Hy} X dy of column X from the record's table."""
    return float(integrals[sid][column])
```

`integral` reads one integral of a state from the table, as a number (`float` turns the text into a number).

```
ratio = {sid: (integral(sid, "int_p3") + integral(sid, "int_p_t"))
         / (2.0 * integral(sid, "int_p0"))
         for sid in nonzero if integral(sid, "int_p0") != 0.0}
closest = min(ratio, key=lambda sid: abs(ratio[sid] - 1.0))
report("ratio closest to 1", f"{ratio[closest]:.6g} ({closest})")
report("range of the ratio", f"{min(ratio.values()):.4f} to {max(ratio.values()):.4f}")
```

`ratio` holds $R = (\int p_3 + \int p_t)/(2\int p_0)$ for every nonzero state (skipping, as a precaution, a state with $\int p_0 = 0$, which would make the division impossible; there is none). `closest` is the state whose ratio is nearest to 1: the `lambda` returns the distance from 1. Output: the ratio closest to 1 is 0.414328 (`N688_lamm2_a00`), and all ratios lie between 0.1072 and 0.4143.

```
history_text = ", ".join(f"{sid}: {ratio[sid]:.6g}" for sid in
                         ("N136_lam0_a00", "N136_lam0_a10", "N136_lam0_a20"))
say("the history N = 136, lambda = 0: " + history_text)
detail = record_entry(SOURCE_REPORT, "ks_integrals_violate_algebraic_condition")[
    "detail"]
reproduces(len(ratio) == len(nonzero)
           and all(abs(r - 1.0) > TOL for r in ratio.values())
           and f"(closest to 1: {ratio[closest]:.6g} at {closest})" in detail
           and history_text in detail,
           "C2 fails also after integration over x0, for every nonzero state",
           SOURCE_REPORT, ["ks_integrals_violate_algebraic_condition"])
```

The ratios of three states of the history are printed as the record prints them: 0.339767, 0.25969 and 0.239714 at the slices 0, 1 and 2. The check requires a ratio for every nonzero state, every ratio away from 1, and the record's text to contain our numbers. Output: PASS C2 fails also after integration over x0, for every nonzero state. (COMPUTED.) So even a source averaged over the hidden direction, a "dimensionally reduced" source, would violate C2.

In [15], the averaged ratio (figure 6).

```
N_COLOURS = {8: "#1baf7a", 136: "#2a78d6", 688: "#eb6834"}
STYLES = {"m2": ("v", ":"), "m1": ("<", "-."), "0": ("o", "-"),
          "p1": (">", "--"), "p2": ("^", (0, (1, 3)))}  # marker, line style
fig, ax = plt.subplots()
```

A colour for each particle number (green, blue, orange), and for each coupling a marker (a triangle pointing down, left, a circle, right, up) and a line style (dotted, dash-dot, solid, dashed, and `(0, (1, 3))`, which means dots of length 1 separated by gaps of 3). One panel of the default size.

```
for n, tag, label in ROWS:
    ids = [f"N{n}_lam{tag}_{s}" for s in SLICES]
    if ids[0] not in ratio:
        continue  # N = 8, lambda = 0: no source
    marker, style = STYLES[tag]
    ax.plot(list(SLICES.values()), [ratio[sid] for sid in ids], marker=marker,
            ls=style, color=N_COLOURS[n], lw=1.3, ms=4)
```

For each of the 15 rows the five state names of the series are built; the series without a source is skipped; the ratio is drawn against the slice values, with the marker and line style of the coupling and the colour of the particle number (`ms` is the marker size).

```
ax.axhline(1.0, color="#e34948", ls="--", lw=1.4)
ax.text(1.0, 0.95, "C2 after integration needs 1", color="#e34948", ha="center",
        va="top", fontsize=9)
```

```
for n, colour in N_COLOURS.items():
    ax.plot([], [], color=colour, lw=2.0, label=f"$N = {n}$")
for tag, label in TAGS:
    marker, style = STYLES[tag]
    ax.plot([], [], color="0.3", marker=marker, ls=style, label=f"$\\lambda = {label}$")
```

A red dashed line at 1 with a short text under it. The two loops draw nothing (`ax.plot([], [])` has no points) but create the entries of the legend: one per colour and one per marker and line style.

```
ax.set_xlabel("slice $a_{4,0}$")
ax.set_ylabel("$(\\int p_3 + \\int p_t) / (2\\int p_0)$")
ax.set_ylim(0.0, 1.1)
ax.legend(fontsize=7, ncol=2, loc="center right")
near = max(max(ratio[f"N{n}_lam{tag}_{s}"] for tag, _ in TAGS)
           - min(ratio[f"N{n}_lam{tag}_{s}"] for tag, _ in TAGS)
           for n in (136, 688) for s in SLICES)  # spread over the couplings
```

Axis labels, the vertical range 0 to 1.1, a legend in two columns. `near` is, over the ten combinations of $N \in \{136, 688\}$ and a slice, the largest difference between the five couplings' ratios (the inner `max(...) - min(...)` is the difference for one combination, the outer `max` the largest of the ten).

```
save_figure(fig, "integrated_ratio",
            "The ratio $(\\int p_3 + \\int p_t)/(2\\int p_0)$ of the pressures "
            "integrated over the patch with the proper-volume weight, for every "
            "nonzero recorded Kohn-Sham state, against the slice $a_{4,0}$ "
            "(colours: particle number; line styles and markers: coupling; pure "
            "numbers). A source averaged over $x_0$ would need the value $1$ (red "

            f"${min(ratio.values()):.3f}$ and ${max(ratio.values()):.3f}$, so even "
            "the average violates condition C2. For $N = 136$ and $N = 688$ the "
            "five couplings give almost the same ratio (they differ by at most "
            f"${near:.4f}$ at one slice), so their lines lie on top of each other.")
```

The caption, joined from its strings as in In [6], inserts the range of the ratios with three decimals, 0.107 to 0.414, and `near` with four decimals, 0.0045. Output: figure 17a.6 and its saved line.

What figure 17a.6 shows. Horizontal axis: the slice $a_{4,0}$; vertical axis: R, a pure number. A source averaged over x_0 would need the red dashed line at 1. The $N = 8$ states lie flat between 0.107 and 0.110 (the same value at every slice; the four nonzero couplings differ slightly); the $N = 136$ states fall from 0.34 to 0.24 and the $N = 688$ states from 0.41 to 0.25 along the history; the five couplings of each of these two N lie on top of each other. All points are far below 1. Section 17.15 explains why: by the integrated conservation law, $R = b_0/\bar{p}_0$ exactly, where $b_0 = [p_0(0) - e^{-6HL}p_0(-L)]/(1 - e^{-6HL})$ is the brane value of p_0 with a tip term; for $N = 136$ and 688 the tip term supplies at most a few per cent of R, for $N = 8$ about a third.

In [16], condition C3 along the history.

```
HISTORY = ["N136_lam0_a00", "N136_lam0_a10", "N136_lam0_a20",
           "N688_lam0_a00", "N688_lam0_a10", "N688_lam0_a20"]
pieces = []
```

```
for sid in HISTORY:
    r, p3, pt = (integral(sid, c) for c in ("int_rho", "int_p3", "int_p_t"))
    pieces.append(f"{sid}: int rho = {r:.6g}, int p3 = {p3:.6g}, int p_t = {pt:.6g}")
    say(pieces[-1])
```

The six states that the record tests. For each, the three integrals are read (the round brackets with `for` make a **generator**, whose three values are given the names `r`, `p3`, `pt`), written as the record writes them, stored, and printed (`pieces[-1]` is the line just added).

```
rho_constant = all(
    abs(integral(a, "int_rho") - integral(b, "int_rho"))
    <= TOL * abs(integral(a, "int_rho"))
    for a, b in (("N136_lam0_a00", "N136_lam0_a10"),
                 ("N688_lam0_a00", "N688_lam0_a10")))
p_equal = all(abs(integral(s, "int_p3") - integral(s, "int_p_t"))
              <= TOL * max(abs(integral(s, "int_p3")), 1.0) for s in HISTORY)
```

`rho_constant` is true only if the energy at slice 1 equals the energy at slice 0, within the relative tolerance, for both particle numbers; `p_equal` only if $\int p_3 = \int p_t$ for all six states (with the tolerance taken relative to $\int p_3$, or absolute when that is below 1). These are the record's own tests of C3.

```
detail = record_entry(SOURCE_REPORT, "ks_history_is_a_prescribed_background")[
    "detail"]
reproduces(not rho_constant and not p_equal and "; ".join(pieces) in detail,
           "C3 fails: along the history rho changes and p3 differs from p_t",
           SOURCE_REPORT, ["ks_history_is_a_prescribed_background"])
```

The check passes when both C3 tests fail and the record prints the same six lines, joined by semicolons. Output:

state	$\int \rho$	$\int p_3$	$\int p_t$
`N136_lam0_a00`	80.2822	23.8133	0
`N136_lam0_a10`	32.3841	10.0397	0
`N136_lam0_a20`	12.4451	4.06205	0
`N688_lam0_a00`	680.441	199.305	0
`N688_lam0_a10`	279.425	84.3387	0
`N688_lam0_a20`	110.387	35.1354	0

(units of m), and PASS C3 fails: along the history rho changes and p3 differs from p_t. (COMPUTED; record check `ks_history_is_a_prescribed_background`.)

In [17], the integrals along the history (figure 7).

```
PARTS = [("int_rho", "$\\int\\rho$", "#2a78d6", "o"),
         ("int_p3", "$\\int p_3$", "#eb6834", "s"),
         ("int_p_t", "$\\int p_t$", "#1baf7a", "^"),
         ("int_p0", "$\\int p_0$", "#4a3aa7", "D")]
fig, axes = plt.subplots(1, 2, figsize=(9.0, 3.8))
```

```
for ax, n in zip(axes, (136, 688)):
    ids = [f"N{n}_lam0_{s}" for s in SLICES]
    for column, label, colour, marker in PARTS:
        ax.plot(list(SLICES.values()), [integral(sid, column) for sid in ids],
                color=colour, marker=marker, lw=1.8, label=label)
    ax.set_xlabel("slice $a_{4,0}$ (the history $a_4 = Hx_4$)")
    ax.set_title(f"$N = {n}$, $\\lambda = 0$")
axes[0].set_ylabel("$2\\,\\mathrm{Vol}_7\\int e^{6Hy} X\\,dy$ (units of $m$)")
axes[1].legend(fontsize=8)
fig.tight_layout()
```

`PARTS` lists, for each of the four integrals, its column, its label, a colour and a marker (circle, square, triangle, diamond). Two panels, one per particle number; in each, the four integrals of the five states with $\lambda = 0$ are drawn against the slice.

```
drop = [integral(f"N{n}_lam0_a00", "int_rho") / integral(f"N{n}_lam0_a20", "int_rho")
        for n in (136, 688)]
```

`drop` is the factor by which the energy falls from the first to the last slice: $80.2822/12.4451 = 6.45$ for $N = 136$ and $680.441/110.387 = 6.16$ for $N = 688$.

```
save_figure(fig, "history_integrals",
            "The energy density and the three pressures of the Kohn-Sham states with "
            "$\\lambda = 0$, integrated over the patch with the proper-volume weight, "
            "at the five slices of the history $a_4 = Hx_4$ (left $N = 136$, right "
            "$N = 688$; vertical axis in units of $m$ with $H = 1$; along the "
            "history 3-space inflates as $e^{a_4}$ and the extra times deflate as "
            "$e^{-a_4}$). The linear member "
            "needs a constant $\\rho$ and equal pressures (condition C3); instead "
            f"$\\int\\rho$ falls by a factor of {drop[0]:.2f} ($N = 136$) and "
            f"{drop[1]:.2f} ($N = 688$) from $a_{{4,0}} = 0$ to $2$, $\\int p_3$ stays "
            "above $\\int p_t = 0$, and $\\int p_0$ is different again.")
```

The caption, joined from its strings as in In [6], inserts both factors with two decimals. In the f-string the subscript is written `a_{{4,0}}`, because inside an f-string a single brace would start a computed piece; the doubled braces print as one pair. Output: figure 17a.7 and its saved line.

What figure 17a.7 shows. Horizontal axis: the slice $a_{4,0}$ of the history $a_4 = Hx_4$ (3-space inflates as e^{a_4}, the extra times deflate as e^{-a_4}); vertical axis: the integrals over the patch in units of m. C3 needs a horizontal blue line ($\int \rho$ constant) and the three pressure lines on top of each other. Instead $\int \rho$ falls by a factor of about 6 over the history, $\int p_3$ (orange) lies well above $\int p_t = 0$ (green, on the axis: without interaction the extra times carry no pressure), and $\int p_0$ (purple) is different again. Section 17.16 shows that the fall of the energy is exactly the work done by the unbalanced pressure, $\int p_3 > \int p_t$.

In [18], the states N = 8.

```
same, p3_equals_pt, p0_differs = True, True, True
for tag in ("m2", "m1", "p1", "p2"):
    first = profiles[f"N8_lam{tag}_a00"]
```

```
    for slice_tag in SLICES:
        prof = profiles[f"N8_lam{tag}_{slice_tag}"]
        same = same and all(np.array_equal(prof[c], first[c]) for c in COLUMNS)
    p3_equals_pt = p3_equals_pt and np.array_equal(first["p3"], first["p_t"])
    p0_differs = p0_differs and float(np.max(np.abs(first["p0"] - first["p3"]))) > 0
```

Three flags start true. For each nonzero coupling of $N = 8$, the profiles of all five slices are compared with the first, column by column and bit for bit (`np.array_equal`); then the cell tests $p_3 = p_t$ exactly and $p_0 \neq p_3$ somewhere. The `and` keeps a flag true only if it stays true for every case.

```
int_p3_n8 = integral("N8_lamp1_a00", "int_p3")  # N = 8, lambda = +lambda_1
int_p0_n8 = integral("N8_lamp1_a00", "int_p0")
say(f"N = 8, lambda = +lambda_1: int p3 = {int_p3_n8:.6g}, int p0 = {int_p0_n8:.6g}")
check(same and p3_equals_pt and p0_differs,
      "N = 8: the same state at every slice, p3 = p_t, but p0 differs from p3")
```

Two integrals of one $N = 8$ state are printed as an example: $\int p_3 = -0.000977659$ and $\int p_0 = -0.00889138$, so p_0 is not p_3. Output: that line and a PASS line. Why these states do not change: the eight zero modes have zero 3-momentum, and the slice enters the Kohn-Sham equations only through the redshifted momentum $ke^{-a_{4,0}}$ (the exact rescaling identity of Chapter 14), so for $k = 0$ nothing changes. They satisfy the part "constant ρ and $p_3 = p_t$" of C3, but they fail C1 and C2 (In [7] and In [9]) and have $p_0 \neq p_3$.

In [19], the states with no source at all.

```
kappa, rho, p0, Lam = sp.symbols("kappa rho p0 Lam", real=True)
NAMES.update({"kappa": kappa, "rho": rho, "p0": p0, "Lam": Lam})

def equation(text):
    """An equation (left == right) of the record as the expression left - right."""
    left, right = text.split("==")
    return parse(left) - parse(right)
```

Four more real symbols (κ, ρ, p_0, Λ) are made and added to the names that `parse` knows (`update` adds pairs to a dictionary). The record writes an equation as `left == right`; `equation` cuts the text at `==` and returns left minus right, which is zero exactly when the equation holds.

```
einstein = equations["einstein"]
x4_equation = equation(einstein["constraint_x4"]["input"]).subs({rho: 0})
x0_equation = equation(einstein["hidden_x0"]["input"]).subs({p0: 0})
difference = sp.expand(x4_equation - x0_equation)  # Lambda cancels
say(f"x4 equation minus x0 equation with rho = p0 = 0: {difference} = 0")
say(f"is the left side positive for real a4' and H > 0? {difference.is_positive}")
```

The record's Einstein constraint `3*ad1^2 + 21*H^2 + Lam == -(kappa*rho)` and hidden equation `-3*ad1^2 + 15*H^2 + Lam == kappa*p0` become expressions with $\rho = 0$ and $p_0 = 0$; their difference, multiplied out, is the derivation of Section 17.6. `.is_positive` asks sympy whether the expression is positive for all allowed values of its symbols (a_4' real, H positive); sympy answers `True`. Output: `6*H**2 + 6*ad1**2 = 0` and `True`.

```
reproduces(difference == 6 * ad1 ** 2 + 6 * H ** 2 and difference.is_positive is True,
           "Einstein gravity: no source at all (T = 0) has no solution for H > 0",
           WL_A4, ["einstein_no_vacuum_solution"])
detail = record_entry(SOURCE_REPORT, "ks_zero_source_states_listed")["detail"]
reproduces(", ".join(zero) in detail and f"{len(zero)} states" in detail,
           "the five states with T = 0 are those listed by the record",
           SOURCE_REPORT, ["ks_zero_source_states_listed"])
```

The first check confirms the difference and its positivity (PROVED; Wolfram report, check `einstein_no_vacuum_solution`). The second confirms that the record lists exactly our five states with $T = 0$: `N8_lam0_a00`, `N8_lam0_a05`, `N8_lam0_a10`, `N8_lam0_a15`, `N8_lam0_a20`. These eight zero modes have zero energy and, without interaction, no source at all; by the first check, "no source" is not admissible either. Output: two PASS lines with their records.

In [20], the last check.

```
names = ["rho_profiles", "c1_map", "violation_profiles", "c2_map", "three_points",
         "integrated_ratio", "history_integrals"]
paths = [output_file(f"{FIGURE_FOLDER}/17a_{k}_{name}.png")
         for k, name in enumerate(names, 1)]
check(all(path.is_file() for path in paths),
      "every figure file of this notebook exists")
all_checks_passed()
```

The seven figure names; `enumerate(names, 1)` counts them from 1, so the paths are `17a_1_rho_profiles.png` to `17a_7_history_integrals.png` in the folder where the notebook wrote them. The check confirms that every file exists, and `all_checks_passed()` prints the last line. Output: PASS every figure file of this notebook exists and ALL 16 CHECKS PASSED (notebook 17a).

The count. The 16 PASS lines are: one in In [2], three in In [4], one each in In [5], In [6], In [7], In [9], In [10], In [12], In [14], In [16], In [18], two in In [19], and one in In [20]. Ten of them reproduce a Revision record and name it.

17.12 Why the states fail: every source must be conserved

Notebook 17a shows THAT the recorded Kohn-Sham ground states fail all three conditions. We now ask WHY. The answer comes from one of the deepest facts about the field equations of gravity.

The Bianchi identity. For every metric, the left-hand side of the field equations has zero covariant divergence:

$$\nabla_\mu {E_{(k)}}^\mu{}_\nu = 0 \quad (k = 1, 2, 3, \text{ every } \nu), \qquad \nabla_\mu(\Lambda\, \delta^\mu_\nu) = 0.$$

The first statement is a theorem about the Lovelock tensors; for the author's metric with an arbitrary $a_4(x_4)$ it is PROVED in the record (checks `E1_divergence_free`, `E2_divergence_free`, `E3_divergence_free` of both the Wolfram and the sympy report). The second holds because Λ is a constant and the covariant derivative of δ^μ_ν is zero (the table δ^μ_ν, 1 on the diagonal and 0 elsewhere, is the same in every coordinate system).

The consequence. Take the covariant divergence of both sides of the field equations:

$$\sum_k \alpha_k \nabla_\mu E_{(k)}{}^\mu{}_\nu + \nabla_\mu(\Lambda\,\delta^\mu_\nu) = \kappa\,\nabla_\mu T^\mu{}_\nu$$

(rule: the same operation on both sides of an equation keeps it true; the divergence of a sum is the sum of the divergences, and a constant factor comes out)

$$0 = \kappa\,\nabla_\mu T^\mu{}_\nu$$

(rule: the Bianchi identity makes every term on the left zero). Since $\kappa \neq 0$: **every source of the field equations is conserved**, $\nabla_\mu T^\mu{}_\nu = 0$. Conservation is NECESSARY.

What the Kohn-Sham states conserve. A field that obeys its own TIME-DEPENDENT field equation in a given metric has a conserved energy-momentum tensor (Section 9.9: it is the Noether identity, which follows from the invariance of the action under a change of coordinates). The Kohn-Sham states are not such solutions: each one solves the instantaneous problem of one slice (the stationary-slice ansatz of Chapter 14), so the Noether argument does not apply to them, and the record proves exactly this much:

- along the hidden direction they are conserved at every point (the y law of Section 17.13, for every self-consistent state: `Revision/kohn_sham/reports/ks-theory-python.json`, check `emt_y_conservation_selfconsistent`; the Rust solver checks it on its grid of points and integrated over the patch: `Revision/kohn_sham/reports/ks-rust-solver.json`, checks `emt_y_conservation_pointwise` and `emt_y_conservation_integrated`);
- in the time direction only the TOTAL energy of the patch obeys the energy-change law (the same theory report, check `emt_x4_component`, which states the law for the energy of the 7-volume; the solver compares the derivative of that energy with respect to a_4, computed by finite differences in a_4, with the law: check `emt_energy_change_dE_da4`). Point by point the time law fails: the instantaneous states carry no energy flux along the hidden direction (their mixed component vanishes), so nothing moves energy from one value of y to another, and the energy at a given y changes along the history differently from what the pressures there demand (Section 17.16 shows the numbers).

So conservation is not SUFFICIENT. Even a source that obeyed every conservation law could fail the field equations, and the Kohn-Sham states, which obey the hidden law everywhere and the time law for their total energy, do fail. The next four sections show precisely what the field equations of the author's metric demand beyond conservation, and why the Kohn-Sham states cannot give it.

17.13 The conservation law in the coordinate y

The covariant divergence. For any metric and any table $T^\mu{}_\nu$,

$$\nabla_\mu T^\mu{}_\nu = \sum_\mu \partial_\mu T^\mu{}_\nu + \sum_{\mu,\lambda} \Gamma^\mu{}_{\mu\lambda}\,T^\lambda{}_\nu - \sum_{\mu,\lambda} \Gamma^\lambda{}_{\mu\nu}\,T^\mu{}_\lambda,$$

with the Christoffel symbols

$$\Gamma^{\lambda}{}_{\mu\nu} = \frac{1}{2}\sum_{\sigma} g^{\lambda\sigma}(\partial_\mu g_{\sigma\nu} + \partial_\nu g_{\sigma\mu} - \partial_\sigma g_{\mu\nu}),$$

where ∂_μ is the partial derivative with respect to the coordinate x_μ and $g^{\lambda\sigma}$ is the inverse metric (the summation index is called σ here, because κ is the strength of gravity). The first sum is the ordinary "change plus outflow"; the two others correct for the stretching and turning of the coordinate directions.

A lemma for a diagonal metric. Write the diagonal entries as $g_{\mu\mu} = \eta_{\mu\mu} f_\mu^2$ with signs $\eta_{\mu\mu} = \pm 1$ and positive scale factors f_μ. For a diagonal metric the inverse is diagonal, $g^{\lambda\lambda} = 1/g_{\lambda\lambda}$, so only $\sigma = \lambda$ survives in the sum:

$$\Gamma^{\lambda}{}_{\mu\nu} = \frac{1}{2g_{\lambda\lambda}}(\partial_\mu g_{\lambda\nu} + \partial_\nu g_{\lambda\mu} - \partial_\lambda g_{\mu\nu}) \quad \text{(no sum over } \lambda\text{)}.$$

Now set $\lambda = \mu$:

$$\Gamma^{\mu}{}_{\mu\nu} = \frac{1}{2g_{\mu\mu}}(\partial_\mu g_{\mu\nu} + \partial_\nu g_{\mu\mu} - \partial_\mu g_{\mu\nu})$$

(rule: replace λ by μ everywhere)

$$= \frac{\partial_\nu g_{\mu\mu}}{2g_{\mu\mu}}$$

(rule: the first and the third term in the bracket are equal and cancel)

$$= \frac{\eta_{\mu\mu}\, 2 f_\mu\, \partial_\nu f_\mu}{2\,\eta_{\mu\mu} f_\mu^2} = \frac{\partial_\nu f_\mu}{f_\mu} = \partial_\nu \ln f_\mu$$

(rule: $g_{\mu\mu} = \eta_{\mu\mu} f_\mu^2$ and the chain rule $\partial_\nu(f_\mu^2) = 2 f_\mu\, \partial_\nu f_\mu$; cancel $2\eta_{\mu\mu} f_\mu$; the derivative of $\ln f$ is f'/f).

The divergence of a diagonal tensor. (Section 9.9 derived this formula for every diagonal metric and applied it in the coordinate x_0; here we apply it in the coordinate y, and we repeat the short derivation so that this section can be read on its own.) Let $T^{\mu}{}_{\nu}$ be diagonal ($T^{\mu}{}_{\nu} = 0$ for $\mu \neq \nu$). In the three sums of the divergence only the terms with a diagonal entry survive: in the first only $\mu = \nu$; in the second only $\lambda = \nu$; in the third only $\lambda = \mu$. So

$$\nabla_\mu T^{\mu}{}_{\nu} = \partial_\nu T^{\nu}{}_{\nu} + \sum_{\mu} \Gamma^{\mu}{}_{\mu\nu}\, T^{\nu}{}_{\nu} - \sum_{\mu} \Gamma^{\mu}{}_{\mu\nu}\, T^{\mu}{}_{\mu}$$

(rule: drop the zero terms; no sum over ν)

$$= \partial_\nu T^{\nu}{}_{\nu} + \sum_{\mu} (\partial_\nu \ln f_\mu)(T^{\nu}{}_{\nu} - T^{\mu}{}_{\mu})$$

(rule: the lemma, and the two sums combined into one).

The author's metric in the coordinate y. In the coordinate y the metric is (Chapter 14)

$$ds^2 = e^{2Hy}\big[e^{2a_4}(dx_1^2+dx_2^2+dx_3^2) - e^{-2a_4}(dx_5^2+dx_6^2+dx_7^2)\big] - dx_4^2 + dy^2,$$

so the scale factors are $f_i = e^{a_4+Hy}$ for 3-space, $f_4 = 1$, $f_t = e^{-a_4+Hy}$ for the extra times and $f_y = 1$. Their logarithms are $\ln f_i = a_4 + Hy$, $\ln f_t = -a_4 + Hy$, $\ln f_4 = \ln f_y = 0$, and their derivatives:

$$\partial_4 \ln f_i = a_4', \quad \partial_4 \ln f_t = -a_4', \quad \partial_y \ln f_i = \partial_y \ln f_t = H, \quad \text{all others } 0.$$

Take a diagonal source $T = \mathrm{diag}(p_3, p_3, p_3, -\rho, p_t, p_t, p_t, p_0)$ whose entries depend on x_4 and y.

The component $\nu = y$. Here $T^y{}_y = p_0$. The three 3-space directions contribute $H(p_0 - p_3)$ each, the three extra times $H(p_0 - p_t)$ each, and x_4 and y contribute nothing (their weight $\partial_y \ln f$ is zero):

$$\nabla_\mu T^\mu{}_y = \partial_y p_0 + 3H(p_0 - p_3) + 3H(p_0 - p_t)$$

(rule: the formula above with $\nu = y$)

$$= p_0' + 6Hp_0 - 3H(p_3 + p_t)$$

(rule: multiply out and collect; the prime on p_0 is $\partial/\partial y$).

The component $\nu = x_4$. Here $T^{x_4}{}_{x_4} = -\rho$:

$$\nabla_\mu T^\mu{}_{x_4} = \partial_4(-\rho) + 3a_4'(-\rho - p_3) + 3(-a_4')(-\rho - p_t)$$

(rule: the formula with $\nu = x_4$; 3-space has weight a_4' and entry p_3, the extra times weight $-a_4'$ and entry p_t)

$$= -\partial_4\rho - 3a_4'\rho - 3a_4'p_3 + 3a_4'\rho + 3a_4'p_t = -\partial_4\rho - 3a_4'(p_3 - p_t)$$

(rule: multiply out; $-3a_4'\rho + 3a_4'\rho = 0$; factor out $-3a_4'$).

The other six components contain only derivatives with respect to $x_1, x_2, x_3, x_5, x_6, x_7$, of which nothing depends, and weights $\partial_{x_1} \ln f = 0$; they vanish identically.

The conservation law. A diagonal source in the author's metric is conserved exactly when

$$\partial_4\rho = -3a_4'\,(p_3 - p_t) \qquad \text{and} \qquad p_0' + 6Hp_0 = 3H(p_3 + p_t).$$

(PROVED: `Revision/kohn_sham/reports/ks-theory-python.json`, checks `emt_y_conservation_selfconsistent` and `emt_x4_component`; recorded in `Revision/kohn_sham/ks-theory.json`, keys `emt.conservationY` and `emt.energyChange`; derived again with sympy in Notebook 17b, In [9].)

The same in the author's coordinate x_0. The record of the a_4 equations writes the law in the coordinate x_0, for the general source with mixed entries (key `generalSource`, equations `conservation_x4` and `conservation_x0`):

$$\nabla_\mu T^\mu{}_{x_4} = -\partial_4\rho - 3a_4'(p_3 - p_t) + \partial_0 q_{04} - 6H\tan z\, q_{04},$$
$$\nabla_\mu T^\mu{}_{x_0} = \partial_0 p_0 + 3H\cot z\,(2p_0 - p_3 - p_t) + \partial_4 q_{40}$$

(PROVED: Wolfram and sympy reports, check `conservation_components`; sympy report, check `json_conservation`; derived again in Notebook 17b, In [7] and In [8]). With $q_{40} = q_{04} = 0$ the two forms agree. By the chain rule of Section 17.4, $\partial_0 = (dy/dx_0)\,\partial_y = \cot z\,\partial_y$, so

$$\partial_0 p_0 + 3H\cot z\,(2p_0 - p_3 - p_t) = \cot z\,[p_0' + 6Hp_0 - 3H(p_3 + p_t)]$$

(rule: write $\partial_0 p_0 = \cot z\, p_0'$ and take out the common factor $\cot z$; $3H \cdot 2p_0 = 6Hp_0$). Since $\cot z > 0$ on the patch, the x_0 law and the y law say the same.

17.14 For a conserved source, C2 says that p0 is flat

The key step. Take a conserved diagonal source and solve the y law for $p_3 + p_t$:

$$p_3 + p_t = \frac{p_0' + 6Hp_0}{3H}$$

(rule: divide both sides of $p_0' + 6Hp_0 = 3H(p_3 + p_t)$ by $3H$, which is not zero). Insert this into the violation of C2:

$$V = p_3 + p_t - 2p_0$$

(rule: the definition of V, Section 17.5)

$$= \frac{p_0' + 6Hp_0}{3H} - 2p_0$$

(rule: replace $p_3 + p_t$ by its value from the conservation law)

$$= \frac{p_0'}{3H} + 2p_0 - 2p_0 = \frac{p_0'}{3H}$$

(rule: split the fraction, $6Hp_0/(3H) = 2p_0$, and cancel). So, for EVERY conserved diagonal source,

$$p_3 + p_t - 2p_0 = \frac{1}{3H}\,\frac{\partial p_0}{\partial y}.$$

(PROVED: Notebook 17b, In [10], with sympy, from the conservation law of In [9].)

What it means.

- For a conserved source, C2 holds at a point exactly when p_0 is flat there ($\partial p_0/\partial y = 0$). C2 is not an extra demand on top of conservation: it is the p_0 part of C1. A conserved source that meets C1 meets C2 automatically.
- For the Kohn-Sham states the violation of C2 is, point by point, the slope of their hidden pressure divided by $3H$. Their p_0 changes by several powers of ten along y (figure 2 of Notebook 17b: the largest $|p_0|$ is 2933 to 2.3×10^6 times the smallest, for $N = 136$, $\lambda = 0$), so V cannot be small.
- The single change of sign of V in figure 17a.3 is now clear: V is zero exactly where p_0 has its maximum. The Kohn-Sham p_0 is negative near the tip, rises steeply, has one maximum (near $y \approx -2.2$ for most slices), and then falls toward the brane; so $V > 0$ on the tip side of the maximum and $V < 0$ on the brane side.
- The identity is COMPUTED on all 70 nonzero states with fourth-order finite differences of the stored profiles: $|p_0'/(3H) - V|$ is at most 1.05×10^{-4} of max|T|, and the difference falls like the fourth power of the step, as an error of the differences must (Notebook 17b, In [11] and In [13]).

A conserved profile that is not flat. Exercise 6 shows that, when $p_3 + p_t = P$ is a constant, every conserved p_0 has the form $p_0 = P/2 + c\,e^{-6Hy}$ with a constant c, and only $c = 0$ satisfies C2. Conservation allows many profiles; the field equations of the author's metric allow only the flat one.

17.15 The integrated law and the averaged condition

The integrated law. Multiply the y law by e^{6Hy}:

$$e^{6Hy}p_0' + 6He^{6Hy}p_0 = 3H\,e^{6Hy}(p_3 + p_t)$$

(rule: multiply both sides by the positive number e^{6Hy})

$$\frac{d}{dy}(e^{6Hy}p_0) = 3H\,e^{6Hy}(p_3 + p_t)$$

(rule: the product rule read backwards, $(e^{6Hy}p_0)' = e^{6Hy}p_0' + 6He^{6Hy}p_0$). Integrate from the tip cutoff $y = -L$ to the brane $y = 0$:

$$e^0\,p_0(0) - e^{-6HL}\,p_0(-L) = 3H\int_{-L}^{0} e^{6Hy}(p_3 + p_t)\,dy$$

(rule: the fundamental theorem of calculus, the integral of a derivative is the difference of the values at the ends). Multiply by $2\,\mathrm{Vol}_7$ and use the notation $\int X$ of Section 17.7:

$$2\,\mathrm{Vol}_7[p_0(0) - e^{-6HL}p_0(-L)] = 3H\Big(\int p_3 + \int p_t\Big).$$

(PROVED from the y law. COMPUTED on the 70 nonzero states with the brane values, tip values and integrals of the record's table: the two sides agree to a relative difference of at most

1.421×10^{-11}; the solver's own relative difference of the same two sides, column `ycons_integrated_rel` (computed from its unrounded numbers and divided by the largest of the terms involved), is at most 1.422×10^{-11}, the value of the solver check `emt_y_conservation_integrated`; Notebook 17b, In [14].)

Why the averaged ratio is not 1. The averaged form of C2 asks for $R = (\int p_3 + \int p_t)/(2\int p_0) = 1$. By the definition of the weighted mean (Section 17.7),

$$\int p_0 = 2\,\mathrm{Vol}_7\,\bar{p}_0\,\frac{1 - e^{-6HL}}{6H}.$$

Divide the integrated law by $2\int p_0$:

$$R = \frac{\int p_3 + \int p_t}{2\int p_0} = \frac{2\,\mathrm{Vol}_7\,[p_0(0) - e^{-6HL}p_0(-L)]/(3H)}{2 \cdot 2\,\mathrm{Vol}_7\,\bar{p}_0\,(1 - e^{-6HL})/(6H)}$$

(rule: the numerator from the integrated law divided by $3H$; the denominator from the line above)

$$= \frac{p_0(0) - e^{-6HL}\,p_0(-L)}{(1 - e^{-6HL})\,\bar{p}_0}$$

(rule: cancel $2\,\mathrm{Vol}_7$; $\frac{1/(3H)}{2/(6H)} = \frac{6H}{6H} = 1$). We call the numerator, divided by $1 - e^{-6HL}$, the **boundary value** of p_0,

$$b_0 = \frac{p_0(0) - e^{-6HL}\,p_0(-L)}{1 - e^{-6HL}}, \qquad R = \frac{b_0}{\bar{p}_0} \quad \text{exactly.}$$

The averaged C2 asks that the boundary value of the hidden pressure equal its weighted mean. That is true for a flat p_0 and false for the Kohn-Sham states, for two different reasons.

- For the states with 3-momentum ($N = 136$ and $N = 688$) the weight e^{6Hy} puts most of the mean in the last stretch before the brane (at $y = -1$ the weight is already $e^{-6} \approx 0.0025$): Notebook 17b, In [15], finds that the last unit, $-1 \le y \le 0$, supplies between 0.812 and 0.932 of the integral of $e^{6Hy}p_0$ for $N = 136$ and between 0.816 and 0.969 for $N = 688$. There their p_0 falls toward the brane, so its boundary value lies below its mean.
- For the $N = 8$ brane zero modes the size of p_0 falls almost like e^{-6Hy} over most of the patch (the shape of the term $c\,e^{-6Hy}$ in Exercise 6), so the product $e^{6Hy}p_0$ is nearly flat there and the mean comes from the whole patch: the last unit supplies only 0.439 to 0.441 of the integral (In [15]). A nearly flat $e^{6Hy}p_0$ makes the mean much larger than the brane value. To see the size, suppose $e^{6Hy}p_0$ were exactly a constant c; then $p_0(0) = c$, while $\bar{p}_0 = cL/[(1 - e^{-6HL})/(6H)] \approx 6HL\,c = 18\,c$ (rule: the integral of the constant c from $-L$ to 0 is cL; then divide by the volume factor of Section 17.7, use $1 - e^{-6HL} \approx 1$, and $H = 1$, $L = 3$). The brane value alone would then give the ratio $1/18 \approx 0.056$; the recorded states give 0.074 (next paragraph). For these states the tip term is not small either: at the tip $e^{6Hy}p_0$ is not tiny compared with its brane value (it has the opposite sign there), so the term $-e^{-6HL}p_0(-L)$ supplies about a third of b_0 (next paragraph). This is the difference from the states with 3-momentum, whose $e^{6Hy}p_0$ is concentrated near the brane.

Is the tip term small? The factor $e^{-6HL} = e^{-18} \approx 1.5 \times 10^{-8}$ is tiny, but near the tip $|p_0|$ is enormous, so the answer depends on the state. Notebook 17b, In [15], measures the share $1 - p_0(0)/b_0$ of R that the tip term supplies: from 4.1×10^{-5} to 0.039 for $N = 136$, from 5.3×10^{-6} to 0.025 for $N = 688$, but 0.31 to 0.33 for the 20 nonzero $N = 8$ states. So $R \approx p_0(\text{brane})/\bar{p}_0$ is a fair description of the states with 3-momentum and a poor one for the brane zero modes: for them the brane value alone would give ratios from 0.074 (the caption of figure 17b.4), and the tip term raises them to the values $R = 0.107$ to 0.110 of figure 17a.6. The exact formula reproduces every ratio of Notebook 17a to a relative difference of 1.4×10^{-11} (Notebook 17b, In [15]); Exercise 5 computes one by hand.

17.16 The time direction: energy exchange and the propagation of the constraint

The energy-change law. For a source that does not depend on x_0, the x_4 law of Section 17.13 reads

$$\rho' = -3a_4' \, (p_3 - p_t)$$

(the prime is d/dx_4). In words: while 3-space inflates ($a_4' > 0$), a 3-space pressure p_3 takes energy out of the source, and while the extra times deflate, an extra-time pressure p_t puts energy in. The volume of the seven directions other than the time is constant (the factors e^{3a_4} and e^{-3a_4} cancel), so, unlike a gas in an ordinary expanding universe, there is no term with ρ itself: only the difference of the two pressures moves the energy. This is the first law of thermodynamics, "change of energy equals minus pressure times change of volume", applied to the two families of directions (an interpretation of the PROVED identity; Section 9.10 works it out).

For the Kohn-Sham gas the record states only the integrated version (`Revision/kohn_sham/ks-theory.json`, key `emt.energyChange`): the energy $E = \int \rho$ of the state changes as

$$\frac{dE}{dx_4} = -3a_4' \Big(\int p_3 - \int p_t \Big).$$

Along the history $a_4 = AHx_4 + a_0$ the slice is $a_{4,0} = a_4(x_4)$, so by the chain rule

$$\frac{dE}{dx_4} = \frac{dE}{da_{4,0}} \cdot \frac{da_4}{dx_4} = AH \, \frac{dE}{da_{4,0}}$$

(rule: the chain rule; $da_4/dx_4 = AH$), and dividing the two expressions for dE/dx_4 by $AH \neq 0$,

$$\frac{dE}{da_{4,0}} = -3 \Big(\int p_3 - \int p_t \Big).$$

(Solver check `emt_energy_change_dE_da4` of the report named in Section 17.12: the derivative that the solver computes from extra self-consistent states at $a_4 \pm \delta$ and $a_4 \pm 2\delta$ around each slice, with $\delta = 0.002$ and fixed occupations, agrees with the right-hand side in all 75 cases; the difference, divided by the larger of the sum of the absolute orbital energies and m, is at most 1.505×10^{-10}.) For $\lambda = 0$, $\int p_t = 0$ and $\int p_3 > 0$, so the energy must FALL along the history. For $N = 136$ at the first slice the rate is $-3 \times 23.8133 = -71.44$ (units of m per unit of $a_{4,0}$). Over the whole history the

energy falls from 80.2822 to 12.4451; Simpson's rule applied to the five recorded rates reproduces the change -67.8372 to a relative error of 2.1×10^{-4}, and for all ten series that change, to at most 2.2×10^{-4} (COMPUTED; Notebook 17b, In [18]; Exercise 7).

Point by point the time law fails. Notebook 17b, In [20], tests $\partial\rho/\partial a_4 = -3(p_3 - p_t)$ at every grid point of the slice $a_{4,0} = 1$, with a fourth-order difference in a_4 over the five slices. For $N = 136$, $\lambda = 0$ it finds at the tip $\partial\rho/\partial a_4 = 82.97$ against $-3(p_3 - p_t) = -474.8$ (opposite signs: the energy density near the tip GROWS along the history while its pressure says it should fall), in the middle ($y = -1.5$) -0.4505 against -1.497, and at the brane -0.002068 against -0.001174. In all ten series with 3-momentum the ratio of the two sides at the tip is negative (-0.327 to -0.106), while the two sides integrated over the patch with the weight e^{6Hy} agree to 1.3×10^{-3}, the accuracy of a difference with step 0.5 (COMPUTED). The reason is the one given in Section 17.12: an instantaneous state has no energy flux q_{04} along y, so the energy of each layer of the patch cannot be balanced by flow into its neighbours; only the total is balanced. A genuinely time-dependent state of the gas would need such a flux, $q_{04} \neq 0$, and C1 forbids it: a further reason why the history is only a prescribed background.

The constraint propagates. Write the constraint and the evolution equation of Section 17.3 as two expressions that must vanish:

$$\mathcal{C} = e_{44}(a_4') + \Lambda + \kappa\rho, \qquad \mathcal{E} = a_4''\,F(a_4') - \kappa(p_3 - p_t).$$

First a fact about e_{44}: its derivative with respect to $a' = a_4'$ is

$$\frac{de_{44}}{da'} = \alpha_1 \cdot 6a' + \alpha_2(-144a'^3 - 240a'H^2) + \alpha_3(2160a'^5 + 2592a'^3H^2 + 2160a'H^4)$$

(rule: differentiate each term of ${E_{(k)}}^{x_4}{}_{x_4}$ of Section 17.3; the derivative of a'^n is na'^{n-1})

$$= 6a'\big[\alpha_1 - \alpha_2(24a'^2 + 40H^2) + \alpha_3(360a'^4 + 432a'^2H^2 + 360H^4)\big] = 6a'\mathcal{Q} = 3a'F$$

(rule: take out the common factor $6a'$; the bracket is $\mathcal{Q}$ of Section 17.3, and $F = 2\mathcal{Q}$). Now differentiate $\mathcal{C}$ along the time, for a source that depends on x_4 only:

$$\frac{d\mathcal{C}}{dx_4} = \frac{de_{44}}{da'}\,a_4'' + \kappa\rho'$$

(rule: the chain rule for $e_{44}(a_4'(x_4))$; Λ is constant)

$$= 3a_4'F\,a_4'' - 3\kappa a_4'(p_3 - p_t)$$

(rule: the fact above, and the energy-change law $\rho' = -3a_4'(p_3 - p_t)$)

$$= 3a_4'\big[a_4''F - \kappa(p_3 - p_t)\big] = 3a_4'\,\mathcal{E}$$

(rule: take out the common factor $3a_4'$). (PROVED: Wolfram report, check `constraint_propagation_bianchi`; sympy report, check `bianchi_x4`; reproduced for all couplings in Notebook 17b, In [17].)

What it means. If the evolution equation holds at all times ($\mathcal{E} = 0$), a constraint that holds at one time holds at all times: this is how the Bianchi identity keeps the field equations consistent. Along the linear member ($a_4'' = 0$, $a_4' = AH$) it gives

$$\frac{d\mathcal{C}}{dx_4} = -3AH\kappa\,(p_3 - p_t).$$

A conserved source with $p_3 \neq p_t$ therefore makes the constraint drift: even if it held at one instant, it would fail at the next. The constraint of the linear member can hold at all times only if $p_3 = p_t$; then $\rho' = 0$ and, with C2, $p_0 = p_3$. For a conserved source along the linear member, C3 therefore reduces to the single demand $p_3 = p_t$: the constant ρ then follows from conservation, and $p_0 = p_3$ from C2. The Kohn-Sham gas at $\lambda = 0$ has $p_t = 0$ and $\int p_3 > 0$: its energy falls along the history, which the linear member forbids.

Summary of Sections 17.12 to 17.16. For a conserved diagonal source in the author's metric:

condition	what it says in general	what it says for a conserved source	the Kohn-Sham states
C1	no component depends on x_0	ρ, p_3, p_t flat; p_0 flat is C2	fail: profiles vary by powers of ten
C2	$p_3 + p_t = 2p_0$	p_0 flat	fail: $V = p_0'/(3H)$ is large
C3	$p_3 = p_t = p_0$, ρ constant	$p_3 = p_t$ (then ρ constant, $p_0 = p_3$)	fail: $\int p_3 > \int p_t$, E falls by a factor of about 6

The Kohn-Sham source is conserved along the hidden direction at every point (y law), and in the time direction only for the total energy of the patch (dE/dx_4 law); it is NOT ADMISSIBLE.

17.17 The equations averaged over the hidden direction: what can and cannot be integrated

Sections 17.4 to 17.16 show that the field equations of the author's metric cannot hold, point by point, with any recorded Kohn-Sham ground state as the source. The Revision record `Revision/field_equations_a4/ks_source/` (script `ks_source_a4.py`, report `reports/ks-source-a4.json` with 23 checks, all PASS) asks the next questions. How far is the source from one that does not depend on x_0? Which weaker, averaged equations can it satisfy? And what do those averaged equations say about $a_4(x_4)$, in particular about the exponential deflation of the extra times? This section derives the answers; Notebook 17b, In [21] to In [23], reproduces the numbers it needs.

The x_0 identity once more. The record proves for every Lovelock order k that ${E_{(k)}}^{x_1}{}_{x_1} + {E_{(k)}}^{x_5}{}_{x_5} - 2{E_{(k)}}^{x_0}{}_{x_0} = 0$ (check `A1_lovelock_identity_x1_plus_x5_equals_2x0`; it is the identity behind C2 in Section 17.5), and that the y law of Section 17.13 gives, for a source that obeys it, $p_3 + p_t - 2p_0 = p_0'(y)/(3H)$ exactly (check `A6_x0_conservation_in_y`; it is Section 17.14). The record then evaluates the y law on all 70 nonzero profiles with fourth-order differences and finds it satisfied to 6.63404×10^{-5} of the largest term (check `B2_x0_conservation_on_every_profile`). This refines the wording of the first record `ks-source-conditions.json` (check `B0_wave1_report_verified`): the recorded states do NOT violate the conservation identity of the hidden direction;

what they violate is $p_3 + p_t = 2p_0$, which is that identity combined with the independence of x_0 (PROVED and COMPUTED, as stated).

How far from an x_0-independent source? The projection mismatch. Among all functions that do not depend on y, which one is closest to a profile $X(y)$? Measure the distance with the volume weight, $D(c) = \int_{-L}^{0} e^{6Hy}\,(X-c)^2\,dy$ for a constant c. Its derivative with respect to c is

$$\frac{dD}{dc} = -2\int_{-L}^{0} e^{6Hy}\,(X-c)\,dy$$

(rule: differentiate under the integral sign; the derivative of $(X-c)^2$ with respect to c is $-2(X-c)$), and it vanishes when

$$\int_{-L}^{0} e^{6Hy} X\,dy = c\int_{-L}^{0} e^{6Hy}\,dy, \qquad c = \frac{\int_{-L}^{0} e^{6Hy} X\,dy}{\int_{-L}^{0} e^{6Hy}\,dy} = \bar{X}$$

(rule: split the integral, take the constant c out, divide by the positive number $\int e^{6Hy}dy$). So the closest flat profile is the weighted mean $\bar{X}$ of Section 17.7; it is called the **orthogonal projection** of X on the flat functions. The record measures the remaining part in two ways: $\mu_1 = \int e^{6Hy}|X-\bar{X}|\,dy / \int e^{6Hy}|X|\,dy$ (the **L1 measure**) and $\mu = \sqrt{D(\bar{X})/D(0)}$ (the **L2 measure**); both are 0 for a flat profile. Over the 70 nonzero states the energy density has μ_1 between 0.583068 and 0.763572 and μ between 0.754082 and 1 (check `B4_hidden_direction_mismatch`; the record prefers the L1 measure, because the L2 measure is dominated by the large values near the tip and so depends more on the tip cutoff). At least about 58 per cent of the energy density deviates from its average: the source is not close to an x_0-independent one (COMPUTED).

The moment equations. Take any one of the field equations of Section 17.3, say the constraint $e_{44} + \Lambda = -\kappa\rho$, multiply it by e^{6Hy} and integrate over the patch:

$$\int_{-L}^{0} e^{6Hy}\,(e_{44}+\Lambda)\,dy = -\kappa\int_{-L}^{0} e^{6Hy}\rho\,dy$$

(rule: the same operation on both sides keeps an equation true)

$$(e_{44}+\Lambda)\,W = -\kappa\,\bar{\rho}\,W, \qquad W = \int_{-L}^{0} e^{6Hy}\,dy = \frac{1-e^{-6HL}}{6H}$$

(rule: the left side does not depend on y and comes out of the integral; on the right, the integral is $W\bar{\rho}$ by the definition of the weighted mean)

$$e_{44} + \Lambda = -\kappa\,\bar{\rho}$$

(rule: divide by $W > 0$). Each field equation gives in this way its **moment**: the same equation with every component of the source replaced by its weighted mean. Every exact solution would satisfy all of them, so they are NECESSARY conditions, weaker than the field equations themselves (PROVED: it is one line of algebra). The combination $x_1 + x_5 - 2x_0$ of the moments reads $0 = \kappa(\bar{p}_3 + \bar{p}_t - 2\bar{p}_0)$, the averaged C2. The record measures its failure by the relative defect $|\bar{p}_3 + \bar{p}_t - 2\bar{p}_0| / (|\bar{p}_3| + |\bar{p}_t| + 2|\bar{p}_0|)$,

which lies between 0.414086 (`N688_lamm2_a00`) and 0.806379 over the 70 nonzero states (check `C1_averaged_algebraic_condition_fails`; reproduced in Notebook 17b, In [21]). No choice of $\kappa \neq 0$ satisfies all the moments: even after averaging, the Kohn-Sham source is not admissible (COMPUTED).

Which moments can hold together. Write $P(X) = \sum_k \alpha_k E_{(k)}{}^{x_4}{}_{x_4}$ evaluated at $a_4'^2 = X$ (the x_4 components contain a_4' only through its square, Section 17.3). In Einstein gravity $P(X) = 3X + 21H^2$. The record proves $3F(a_4') = 2\,dP/dX$ at $X = a_4'^2$ for all couplings (check `A3_F_equals_two_thirds_dP_dX`; in Einstein gravity $3 \times 2 = 2 \times 3$), the fact $de_{44}/da' = 3a'F$ of Section 17.16 in another form. The averaged source obeys the averaged energy relation $d\bar{\rho}/da_4 = -3(\bar{p}_3 - \bar{p}_t)$, because the time law holds for the total energy of the patch (check `C2_averaged_energy_relation`: the solver's derivative agrees with it to 1.53537×10^{-10}, Simpson's rule over the slices to 2.70425×10^{-4}, and there are no Fermi-level crossings along the history). Then the derivation of Section 17.16 goes through with the averages:

$$\frac{d}{dx_4}\Big[P(a_4'^2) + \Lambda + \kappa\bar{\rho}(a_4)\Big] = 3a_4'\Big[a_4''F(a_4') - \kappa(\bar{p}_3 - \bar{p}_t)\Big]$$

(PROVED: check `A4_constraint_propagation_with_averaged_source`). So the x_4 moment (the constraint) and the $x_1 - x_5$ moment (the evolution equation) are consistent with each other. The x_0 moment is not. In Einstein gravity the x_4 and x_0 moments read

$$3a_4'^2 + 21H^2 + \Lambda = -\kappa\bar{\rho}, \qquad 15H^2 - 3a_4'^2 + \Lambda = \kappa\bar{p}_0;$$

adding them gives

$$36H^2 + 2\Lambda = \kappa(\bar{p}_0 - \bar{\rho})$$

(rule: add the two equations side by side and move $-\kappa\bar{\rho}$ to the right; $3a_4'^2 - 3a_4'^2 = 0$, $21H^2 + 15H^2 = 36H^2$). The left side is a constant, so $\bar{p}_0 - \bar{\rho}$ would have to stay constant along the history. In the ten series with 3-momentum it changes by 0.909317 to 0.915045 of its largest value (check `C3_x0_moment_inconsistent_with_history`): every set of moments that contains the x_0 moment is inconsistent for them (COMPUTED). For the $N = 8$ states the averages do not change along the history, but their averaged C2 still fails.

The approximation, stated. The record therefore keeps the consistent pair, the x_4 moment and the $x_1 - x_5$ moment, and drops the x_0 moment and the $x_1 + x_5 - 2x_0$ moment. This is an APPROXIMATION (ASSUMED), and its error is not small: the dropped averaged C2 fails by the defects 0.41 to 0.81 quoted above, and the dropped x_0 moment, evaluated along the solved histories, fails by 0.109607 to 1.87301 of the largest term of that equation (check `D7_dropped_x0_moment_residual_and_adiabaticity`). Everything below holds only within this approximation, for the zero-temperature instantaneous states at the computed slices $0 \leq a_4 \leq 2$.

The first integral. For $a_4' \neq 0$ the pair is equivalent to the single first-order equation $P(a_4'^2) + \Lambda = -\kappa\bar{\rho}(a_4)$ (the bracket of the identity above is constant, and the constraint makes the constant zero). In Einstein gravity, with the initial rate $a_4'(0) = H$ (the rate of the history on which the states were computed) and the **source strength** $\sigma_0 = \kappa\bar{\rho}(0)/H^2$, the constraint at $a_4 = 0$ fixes Λ:

$$3H^2 + 21H^2 + \Lambda = -\sigma_0 H^2 \quad \Longrightarrow \quad \Lambda = -24H^2 - \sigma_0 H^2$$

(rule: insert $a_4' = H$ and $\kappa\bar{\rho}(0) = \sigma_0 H^2$; move the numbers to the right). Insert this Λ into the constraint at a later a_4:

$$3a_4'^2 + 21H^2 - 24H^2 - \sigma_0 H^2 = -\kappa\bar{\rho}(a_4) = -\sigma_0 H^2 \, \frac{\bar{\rho}(a_4)}{\bar{\rho}(0)}$$

(rule: $\kappa = \sigma_0 H^2/\bar{\rho}(0)$ by the definition of σ_0)

$$\Big(\frac{a_4'}{H}\Big)^2 = 1 + \frac{\sigma_0}{3}\Big(1 - \frac{\bar{\rho}(a_4)}{\bar{\rho}(0)}\Big)$$

(rule: move $-3H^2 - \sigma_0 H^2$ to the right, divide by $3H^2$). (PROVED; the record reproduces it at every slice reached by every Einstein case, that is up to the turning point where a case halts, to 1.6946×10^{-15}, check `D2_einstein_first_integral`.) The gas changes $a_4'^2$ only through the fraction $1 - \bar{\rho}(a_4)/\bar{\rho}(0)$ of its averaged energy density that it has lost. Over the computed range the record finds that $a_4'^2$ changes by at most $0.281661\,|\sigma_0|H^2$ (check `D5_einstein_sign_of_the_effect`; among the four integrated series with 3-momentum listed below, the largest change belongs to $N = 136$, $\lambda = 0$, whose lost fraction at $a_4 = 2$ is therefore $3 \times 0.281661 = 0.845$).

What can be integrated, and what it gives. The record integrates the pair for three theories of gravity (Einstein, $\alpha_1 = 1$; Einstein-Gauss-Bonnet, $\alpha_2 H^2 = 1/80$; a cubic Lovelock case, $\alpha_2 H^2 = 1/80$, $\alpha_3 H^4 = 1/4000$), five series of states (four of the ten series with 3-momentum, $N = 136$, $\lambda = 0$ and $N = 688$, $\lambda = 0, \pm\lambda_2$, and the series $N = 8$, $+\lambda_2$; the other six series with 3-momentum, $N = 136$ with $\lambda = \pm\lambda_1, \pm\lambda_2$ and $N = 688$ with $\lambda = \pm\lambda_1$, are not integrated; record table `results/ks-source-a4-cases.csv`) and seven parameter choices ($\sigma_0 = \pm 10, \pm 1, \pm 1/10$, and $\Lambda = 0$), by two methods: the first integral, and a fourth-order Runge-Kutta integration of the evolution equation with a separately interpolated source. The two agree to 5.49953×10^{-4} (check `D1_two_integration_methods_agree`). Between the slices $\bar{\rho}$ is taken from the cubic Hermite interpolant with the exact slopes $-3(\bar{p}_3 - \bar{p}_t)$. The results (COMPUTED, within the approximation):

- For $N = 136$, $\lambda = 0$ in Einstein gravity, $a_4'(2)/a_4'(0) = 1.95362$ for $\sigma_0 = 10$, 1.1321 for $\sigma_0 = 1$ and 0.847549 for $\sigma_0 = -1$. A positive $\kappa\bar{\rho}$ speeds the deflation of the extra times up; a negative one slows it down (Notebook 17b, In [22], reproduces these three numbers from the first integral; figure 17b.6).
- With $\Lambda = 0$ the constraint at $a_4 = 0$ needs $\sigma_0 = -24$ in Einstein gravity ($\sigma_0 < 0$, that is $\kappa\bar{\rho}(0) < 0$, in all three theories; for the four integrated series with 3-momentum $\bar{\rho}(0) > 0$, so this forces $\kappa < 0$, record table, column `kappa`), and for these four series the deflation HALTS: for $N = 136$, $\lambda = 0$, a_4' reaches 0 at the turning point $a_4 = 0.149623$ (Einstein), 0.0724197 (Einstein-Gauss-Bonnet), 0.102772 (cubic), and the three integrated series with $N = 688$ halt likewise, at 0.151681 to 0.151697 (Einstein), 0.0733735 to 0.0733808 (Einstein-Gauss-Bonnet) and 0.104149 to 0.104159 (cubic) (check `D3_lambda_zero_cases_halt`; Notebook 17b, In [22], finds the Einstein value for $N = 136$, and 0.397998 for $\sigma_0 = -10$, by bisection). The integration stops at the turning point; what follows it is not computed (OPEN).

- In Einstein-Gauss-Bonnet gravity $F = 1 - \frac{3}{5}a_4'^2/H^2$ vanishes at $a_4'^2 = \frac{5}{3}H^2$ (check `D0_gravity_branches`; in Einstein gravity $F = 2$ and in the cubic case $F > 0$ never vanish). For $\sigma_0 = 1$ and $\sigma_0 = 10$ the first integral drives $a_4'^2$ up to this **branch point** inside the computed range, where the evolution equation cannot be solved for a_4'' (8 cases: the four integrated series with 3-momentum, two strengths each): for $N = 136$, $\lambda = 0$ at $a_4 = 0.249607$ ($\sigma_0 = 1$) and 0.0226924 ($\sigma_0 = 10$) (check `D6_branch_points_only_for_egb`). For $\sigma_0 = 1/10$ these four series stay regular up to $a_4 = 2$, where a_4'/H is between 1.07629 and 1.07705, and the $N = 8$ series keeps $a_4' = H$ for every strength (record table, columns `event` and `rate_end`).
- For the $N = 8$ states the averages do not change with a_4 and $\bar{p}_3 = \bar{p}_t$, so the evolution equation gives $a_4'' = 0$: exactly the linear member $a_4 = A_0 H x_4 + a_0$, with the rate A_0 chosen initially and Λ absorbing $\kappa\bar{\rho}$ (check `D4_constant_source_gives_linear_member`); their averaged C2 still fails.

What cannot be integrated, or was not computed. The full coupled problem, the author's metric with the Kohn-Sham source, has no solution at all (C1 fails), so nothing about a_4 is DERIVED from it (PROVED, Sections 17.4 to 17.14). The x_0 moment cannot be kept (shown above). Not computed (OPEN): the source beyond $a_4 = 2$, where no Kohn-Sham states exist (the record states only a CONDITIONAL: if $\bar{\rho}$ tended to 0 there, Einstein gravity would give $a_4'^2 \to (-\Lambda - 21H^2)/3$, a late-time exponential deflation at a rate set by Λ and H alone); the evolution after a turning point; the six series with 3-momentum that are not integrated; thermal states (only the ground states, at zero temperature, are used); the time-dependent, non-adiabatic problem; and a source with the profile the equations require, or a metric with x_0-dependent warp functions that could carry the Kohn-Sham profile.

So, does the dirac16complex source drive the exponential deflation of the extra times? Exactly: the question has no solution to examine, because no recorded Kohn-Sham ground state is an admissible source. Within the stated approximation: no. The equations are unchanged under $x_4 \to -x_4$, because F and P contain a_4' only through even powers (check `A3_F_equals_two_thirds_dP_dX`); that reversal turns deflation of the extra times into inflation, so the sign of the rate and its size are initial data, and Λ is fixed by them through the constraint. The gas only modifies a deflation that is already there, by a bounded amount set by the energy it loses; with $\Lambda = 0$ it even halts it at a turning point, where the integration stops (what follows is not computed). Exponential deflation at a constant rate is allowed (the $N = 8$ states give exactly the linear member) but not selected. This is the answer of the record `Revision/field_equations_a4/ks_source/README.md`, reproduced here step by step.

17.18 Example: the conservation laws, the averaged equations, and why the states fail

The second notebook makes Sections 17.12 to 17.17 concrete. It first checks that the Kohn-Sham source rests on the author's eight real 16×16 gamma matrices, the very file that the Rust solver read; then it derives with sympy the covariant divergence of a general source in the author's metric, in the coordinate x_0 and in the coordinate y, and compares it with the two Revision records; it proves $V = p_0'/(3H)$ and $d\mathcal{C}/dx_4 = 3a_4'\mathcal{E}$; and it tests the identities on the 75 recorded ground states, point by point with a convergence study, integrated over the patch, and along the deflating history, where it also shows that the time law fails point by point; finally it computes the hidden-direction averages, the defect of the averaged C2 and the first integral of the averaged equations of Einstein

gravity, and reproduces the record's rates and turning points. It prints 20 PASS lines and draws six figures. It runs in about 20 seconds on a typical laptop and needs no Rust.

17.19 How to run Notebook 17b

Step 1. What this notebook does and what it needs.

Notebook 17b (The conservation laws and the source conditions: why the Kohn-Sham states fail) is the file `Revision/textbook/notebooks/17b_conserved_sources.ipynb` of the repository Dirac_claude. It checks that the Kohn-Sham source of chapter 17 rests on the eight real 16 x 16 gamma matrices of the author (the very file the Rust solver read), derives with sympy the conservation law of a source in the author's metric, in the coordinate x0 and in the hidden coordinate y, and compares it with the Revision records. It proves that for a conserved source the violation p3 + p_t - 2 p0 of condition C2 equals the slope of p0 along y divided by 3H, and that the time derivative of the constraint is 3 a4' times the evolution equation, so that the linear member needs p3 = p_t. It then tests these identities on the 75 recorded Kohn-Sham ground states: point by point with fourth-order differences and a convergence study, integrated with the brane and tip values, and along the deflating history with Simpson's rule. The Kohn-Sham states obey the conservation law of the hidden direction at every point and the energy law of the time direction for the total energy of the patch (not point by point), and still fail the source conditions. Finally it averages the source over the hidden direction and integrates the averaged a4 equations of Einstein gravity with their first integral, an approximation whose numbers it checks against the Revision record. Six teaching plots. It needs a computer with Windows 11, macOS or Linux, an internet connection for the installation, the program Git, and Python 3.12 or newer (the notebooks were built with Python 3.14.5) with these packages at exactly these versions: numpy 2.4.6, sympy 1.14.0, mpmath 1.3.0, matplotlib 3.11.0, jupyterlab 4.4.10, nbformat 5.10.4, nbclient 0.10.2, ipykernel 7.1.0 and nbconvert 7.16.6. The notebook itself imports numpy, sympy and matplotlib; the other packages run Jupyter, the program that shows and runs notebooks. It does not need Rust.

Step 2. Install Git and Python (once per computer).

A terminal is the window in which you type commands: on Windows the app Windows PowerShell (or Terminal), on macOS the app Terminal (it runs the shell zsh), on Linux any terminal (it runs the shell bash). Type every command of this section into a terminal exactly as printed, one line at a time, and press Enter after each line.

Windows: download Git from https://git-scm.com/download/win and install it with the default choices. Download Python from https://www.python.org/downloads/ and run the installer; in its first window tick the box "Add python.exe to PATH" before you click "Install Now".

macOS: download Python from https://www.python.org/downloads/ and run the installer. Then open the app Terminal and run this command, which installs Git and the compiler tools:

macOS (zsh):

```
xcode-select --install
```

Linux (Debian or Ubuntu; other distributions have packages of the same names): run these two commands:

Linux (bash):

```
sudo apt update
sudo apt install git python3 python3-venv
```

Then close the terminal and open a NEW one (a terminal opened before the installation does not know the new programs), and check the version of Python; it must print 3.12 or a higher number:

Windows (PowerShell):

```
py -3 --version
```

macOS (zsh) and Linux (bash):

```
python3 --version
```

If an older Linux prints a lower number (Ubuntu 22.04 has Python 3.10), install Python 3.12 with the following three commands, and in Step 3 type `python3.12` instead of `python3` in the command that creates the environment:

Linux (bash), only when the version is too low:

```
sudo add-apt-repository ppa:deadsnakes/ppa
sudo apt update
sudo apt install python3.12 python3.12-venv
```

Step 3. Get the repository and install the packages (once per computer).

The commands below download the repository (a few hundred megabytes; the folder then needs up to about 1 GB of disk space) into the folder Dirac_claude inside your home folder, create a private Python environment in the folder dirac-book-env inside your home folder (a private environment is a folder with its own copy of Python and of the packages, so that nothing else on your computer is changed), activate it (from then on the commands `python` and `jupyter` typed in this terminal are those of the environment, and the prompt starts with (dirac-book-env)), and install the packages at the pinned versions (this downloads about 90 MB and takes a few minutes; the environment takes about 400 MB of disk space). If you have done this step before, for this or for another notebook, skip it and go to Step 4; to get the newest version of the repository, run `git pull` in the repository folder after Step 4.

Windows (PowerShell):

```
cd $HOME
git clone https://github.com/once-ere/Dirac_claude.git
py -3 -m venv "$HOME\dirac-book-env"
Set-ExecutionPolicy -ExecutionPolicy RemoteSigned -Scope Process -Force
& "$HOME\dirac-book-env\Scripts\Activate.ps1"
python -m pip install --upgrade pip
python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
```

The line with `Set-ExecutionPolicy` allows PowerShell to run the activation script in this one window only; it changes nothing permanently.

macOS (zsh):

```
cd ~
git clone https://github.com/once-ere/Dirac_claude.git
python3 -m venv ~/dirac-book-env
source ~/dirac-book-env/bin/activate
python -m pip install --upgrade pip
python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
```

Linux (bash):

```
cd ~
git clone https://github.com/once-ere/Dirac_claude.git
python3 -m venv ~/dirac-book-env
source ~/dirac-book-env/bin/activate
python -m pip install --upgrade pip
python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
```

Step 4. In every new terminal: activate the environment and go into the repository folder.

Every later step starts in the repository folder with the environment active. Run these lines whenever you open a new terminal (they do no harm if the environment is already active):

Windows (PowerShell):

```
Set-ExecutionPolicy -ExecutionPolicy RemoteSigned -Scope Process -Force
& "$HOME\dirac-book-env\Scripts\Activate.ps1"
cd "$HOME\Dirac_claude"
```

macOS (zsh) and Linux (bash):

```
source ~/dirac-book-env/bin/activate
cd ~/Dirac_claude
```

Step 5. Run the notebook in JupyterLab.

In the repository folder, with the environment active, run these two lines (the first one goes into the folder of the notebooks):

Windows, macOS and Linux:

```
cd Revision/textbook/notebooks
jupyter lab 17b_conserved_sources.ipynb
```

JupyterLab opens in your web browser and shows the notebook (if no browser window opens, copy the address that starts with `http://localhost:8888/lab` from the terminal into the address bar of your browser). The name at the top right of the notebook must read Python 3 (ipykernel). Choose the menu Run > Run All Cells. While a cell runs, the label to its left shows `[*]`; when it has finished, the label shows a number. The notebook has finished when the last code cell shows a number; this takes about 20 seconds on a typical laptop. Scroll to the end and compare the last printed lines with the lines in the step "What the notebook writes and what you must see" below. To keep the results, save the notebook (menu File > Save Notebook). To stop JupyterLab, choose the menu File > Shut Down, or press Ctrl+C twice in the terminal.

Step 6. Or run the notebook without a browser (headless).

In the repository folder, with the environment active, run:

Windows, macOS and Linux:

```
cd Revision/textbook/notebooks
jupyter nbconvert --to notebook --execute --inplace 17b_conserved_sources.ipynb
```

This runs every cell from the top to the bottom and saves the results into the notebook file. A failed check stops it with an error message that contains AssertionError and the name of the check. If the command ends with a line that starts with `[NbConvertApp] Writing` and shows no error, every check passed; open the notebook with `jupyter lab 17b_conserved_sources.ipynb` (in the same folder, without running the cells again) to read the printed lines and see the figures.

Step 7. What the notebook writes and what you must see.

The notebook writes (or overwrites) these files:

- `Revision/textbook/figures/17b.captions.json`
- `Revision/textbook/figures/17b_1_eight_gammas.png`
- `Revision/textbook/figures/17b_2_slope_identity.png`
- `Revision/textbook/figures/17b_3_difference_order.png`
- `Revision/textbook/figures/17b_4_brane_and_mean.png`
- `Revision/textbook/figures/17b_5_energy_exchange.png`
- `Revision/textbook/figures/17b_6_first_integral.png`

It changes no other file of the repository; running it headless or saving it in JupyterLab also rewrites the notebook file itself. It does not use the internet while it runs. The files it writes are the same files that are stored in the repository (on another computer a figure may differ in a few bytes, which is harmless). To get the stored versions back, run this command in the repository folder (it also undoes every change you made yourself in the folder Revision/textbook):

Windows, macOS and Linux:

```
git checkout -- Revision/textbook
```

Every check of the notebook prints a line that starts with PASS. At the end of the notebook (the output of its last code cell) you must see exactly these lines:

```
PASS every figure file of this notebook exists
ALL 20 CHECKS PASSED (notebook 17b)
```

and the notebook must show 6 figures below the cells that draw them.

Step 8. If something goes wrong.

- "ModuleNotFoundError: No module named ..." in the notebook: JupyterLab was started without the environment. Stop it (menu File > Shut Down), do Step 4, and start it again. If the error remains, another Python installation has registered its own kernel called python3; with the environment active, run the following command and start JupyterLab again:

```
python -m ipykernel install --user --name python3
```

- "FileNotFoundError: The repository folder was not found": the notebook was opened from a copy outside the repository. Open the file `Revision/textbook/notebooks/17b_conserved_sources.ipynb` inside the folder Dirac_claude.
- "fatal: destination path 'Dirac_claude' already exists" in Step 3: the repository was downloaded before; skip the line with `git clone`.
- Windows: "running scripts is disabled on this system": run the line with `Set-ExecutionPolicy` and then the activation line again. "py is not recognized": use `python` instead of `py -3`; "python is not recognized": install Python again and tick "Add python.exe to PATH".
- Linux: "ensurepip is not available" when the environment is created: run `sudo apt install python3-venv` and repeat Step 3.
- "jupyter is not recognized" or "command not found: jupyter": the environment is not active; do Step 4. If the environment is active and the message stays, the programs jupyter-lab and jupyter-nbconvert are not in the folders where the terminal looks for programs (`python -m jupyter` does not help then: it has to find the same programs). Start them through Python itself, in the folder of the notebook: the first command below does what `jupyter lab` does, the second what the headless command does:

```
python -m jupyterlab 17b_conserved_sources.ipynb
python -m nbconvert --execute --inplace 17b_conserved_sources.ipynb
```

- Windows: the headless run prints a RuntimeWarning that mentions the "Proactor event loop" and zmq: this is a message of the package pyzmq, not an error; the run continues normally.
- A red box with "Matplotlib is building the font cache; this may take a moment." in the first run after the installation: this is a message, not an error; the run continues and the message does not come again.

- An AssertionError names a check that failed: choose the menu Kernel > Restart Kernel and Run All Cells; if it fails again, install the packages again with the pip commands of Step 3, because a different package version can change the last digits of a result.
- "FileNotFoundError" naming gammas.json, a report or a profile file: the notebook reads the Revision records of the repository. Run it inside the folder Revision/textbook/notebooks of a complete copy of the repository made with git clone, not on a copy of the notebook file alone.
- the check of the sha256 fingerprint of gammas.json fails: the file was changed, for example by an editor or a tool that converted its line endings. Restore it with the command below, run in the repository folder.

```
git checkout HEAD Revision/algebra/gammas.json
```

17.20 Notebook 17b: complete text

This section prints the complete text of the notebook file `Revision/textbook/notebooks/17b_conserved_sources.ipynb`: every cell in order, with the output that the stored, executed notebook holds. A text cell (Jupyter calls it a markdown cell) is printed in a frame after the label Text cell. A code cell is printed after the label In [k], where k is the number that Jupyter gives the cell when it runs it; the text that the cell prints follows after the label Out [k], and every figure that the cell draws follows as a figure with its caption.

Text cell:

```
## 1. What this notebook computes

Notebook 17a showed that no recorded Kohn-Sham ground state of dirac16complex is an
admissible source of the author's metric: the states fail the three source
conditions C1, C2, C3 of the $a_4$ equations. This notebook asks WHY, and the
answer is the **conservation law** of energy and momentum. Every source of the
field equations must be conserved; the Kohn-Sham states obey the conservation law
of the hidden direction at every point, and the energy law of the time direction
only for the total energy of the patch; and for a conserved source the conditions
take a very simple form. The notebook

- checks that the Kohn-Sham source is built on the author's eight REAL
  $16 \times 16$ gamma matrices (the very file that the Rust solver read);
- derives with sympy the conservation law of a source in the author's metric, in
  the coordinate $x_0$ and in the hidden coordinate $y$, and compares it with the
  Revision records;
- PROVES that for a conserved source the violation of C2 is the slope of $p_0$:
  $p_3 + p_t - 2p_0 = p_0'(y)/(3H)$; so C2 holds exactly where $p_0$ is flat;
- PROVES that the time derivative of the constraint equation is $3a_4'$ times the
  evolution equation, so that the linear member $a_4 = AHx_4$ needs $p_3 = p_t$;
- tests these identities on the 75 recorded Kohn-Sham ground states: point by
  point (with a convergence study of the differences), integrated over the
  hidden direction, and along the deflating history, where only the energy of the
  whole patch obeys the time law;
- averages the source over the hidden direction, shows that the averaged C2 still
  fails, and integrates the averaged $a_4$ equations of Einstein gravity with
```

```
  their first integral (an APPROXIMATION, as the Revision record states);
- draws six teaching plots. It takes about twenty seconds.
```

Text cell:

```
## 2. How to run this notebook

**Step 1. What this notebook does and what it needs.**

Notebook 17b (The conservation laws and the source conditions: why the Kohn-Sham states
fail) is the file ‘Revision/textbook/notebooks/17b_conserved_sources.ipynb‘ of the
repository Dirac_claude. It checks that the Kohn-Sham source of chapter 17 rests on the
eight real 16 x 16 gamma matrices of the author (the very file the Rust solver read),
derives with sympy the conservation law of a source in the author’s metric, in the
coordinate x0 and in the hidden coordinate y, and compares it with the Revision records.
It proves that for a conserved source the violation p3 + p_t - 2 p0 of condition C2
equals the slope of p0 along y divided by 3H, and that the time derivative of the
constraint is 3 a4’ times the evolution equation, so that the linear member needs p3 =
p_t. It then tests these identities on the 75 recorded Kohn-Sham ground states: point by
point with fourth-order differences and a convergence study, integrated with the brane
and tip values, and along the deflating history with Simpson’s rule. The Kohn-Sham states
obey the conservation law of the hidden direction at every point and the energy law of
the time direction for the total energy of the patch (not point by point), and still fail
the source conditions. Finally it averages the source over the hidden direction and
integrates the averaged a4 equations of Einstein gravity with their first integral, an
approximation whose numbers it checks against the Revision record. Six teaching plots. It
needs a computer with Windows 11, macOS or Linux, an internet connection for the
installation, the program Git, and Python 3.12 or newer (the notebooks were built with
Python 3.14.5) with these packages at exactly these versions: numpy 2.4.6, sympy 1.14.0,
mpmath 1.3.0, matplotlib 3.11.0, jupyterlab 4.4.10, nbformat 5.10.4, nbclient 0.10.2,
ipykernel 7.1.0 and nbconvert 7.16.6. The notebook itself imports numpy, sympy and
matplotlib; the other packages run Jupyter, the program that shows and runs notebooks. It
does not need Rust.

**Step 2. Install Git and Python (once per computer).**

A terminal is the window in which you type commands: on Windows the app Windows
PowerShell (or Terminal), on macOS the app Terminal (it runs the shell zsh), on Linux any
terminal (it runs the shell bash). Type every command of this section into a terminal
exactly as printed, one line at a time, and press Enter after each line.

Windows: download Git from https://git-scm.com/download/win and install it with the
default choices. Download Python from https://www.python.org/downloads/ and run the
installer; in its first window tick the box "Add python.exe to PATH" before you click
"Install Now".

macOS: download Python from https://www.python.org/downloads/ and run the installer. Then
open the app Terminal and run this command, which installs Git and the compiler tools:

macOS (zsh):

    xcode-select --install
```

Linux (Debian or Ubuntu; other distributions have packages of the same names): run these two commands:

Linux (bash):

```
    sudo apt update
    sudo apt install git python3 python3-venv
```

Then close the terminal and open a NEW one (a terminal opened before the installation does not know the new programs), and check the version of Python; it must print 3.12 or a higher number:

Windows (PowerShell):

```
    py -3 --version
```

macOS (zsh) and Linux (bash):

```
    python3 --version
```

If an older Linux prints a lower number (Ubuntu 22.04 has Python 3.10), install Python 3.12 with the following three commands, and in Step 3 type ‘python3.12‘ instead of ‘python3‘ in the command that creates the environment:

Linux (bash), only when the version is too low:

```
    sudo add-apt-repository ppa:deadsnakes/ppa
    sudo apt update
    sudo apt install python3.12 python3.12-venv
```

Step 3. Get the repository and install the packages (once per computer).

The commands below download the repository (a few hundred megabytes; the folder then needs up to about 1 GB of disk space) into the folder Dirac_claude inside your home folder, create a private Python environment in the folder dirac-book-env inside your home folder (a private environment is a folder with its own copy of Python and of the packages, so that nothing else on your computer is changed), activate it (from then on the commands ‘python‘ and ‘jupyter‘ typed in this terminal are those of the environment, and the prompt starts with (dirac-book-env)), and install the packages at the pinned versions (this downloads about 90 MB and takes a few minutes; the environment takes about 400 MB of disk space). If you have done this step before, for this or for another notebook, skip it and go to Step 4; to get the newest version of the repository, run ‘git pull‘ in the repository folder after Step 4.

Windows (PowerShell):

```
    cd $HOME
    git clone https://github.com/once-ere/Dirac_claude.git
    py -3 -m venv "$HOME\dirac-book-env"
    Set-ExecutionPolicy -ExecutionPolicy RemoteSigned -Scope Process -Force
    & "$HOME\dirac-book-env\Scripts\Activate.ps1"
    python -m pip install --upgrade pip
    python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
    python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
```

```
    python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
```

The line with ‘Set-ExecutionPolicy‘ allows PowerShell to run the activation script in this one window only; it changes nothing permanently.

macOS (zsh):

```
    cd ~
    git clone https://github.com/once-ere/Dirac_claude.git
    python3 -m venv ~/dirac-book-env
    source ~/dirac-book-env/bin/activate
    python -m pip install --upgrade pip
    python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
    python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
    python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
```

Linux (bash):

```
    cd ~
    git clone https://github.com/once-ere/Dirac_claude.git
    python3 -m venv ~/dirac-book-env
    source ~/dirac-book-env/bin/activate
    python -m pip install --upgrade pip
    python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
    python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
    python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
```

Step 4. In every new terminal: activate the environment and go into the repository folder.

Every later step starts in the repository folder with the environment active. Run these lines whenever you open a new terminal (they do no harm if the environment is already active):

Windows (PowerShell):

```
    Set-ExecutionPolicy -ExecutionPolicy RemoteSigned -Scope Process -Force
    & "$HOME\dirac-book-env\Scripts\Activate.ps1"
    cd "$HOME\Dirac_claude"
```

macOS (zsh) and Linux (bash):

```
    source ~/dirac-book-env/bin/activate
    cd ~/Dirac_claude
```

Step 5. Run the notebook in JupyterLab.

In the repository folder, with the environment active, run these two lines (the first one goes into the folder of the notebooks):

Windows, macOS and Linux:

```
    cd Revision/textbook/notebooks
    jupyter lab 17b_conserved_sources.ipynb
```

JupyterLab opens in your web browser and shows the notebook (if no browser window opens, copy the address that starts with ‘http://localhost:8888/lab‘ from the terminal into the address bar of your browser). The name at the top right of the notebook must read Python 3 (ipykernel). Choose the menu Run > Run All Cells. While a cell runs, the label to its left shows ‘[*]‘; when it has finished, the label shows a number. The notebook has finished when the last code cell shows a number; this takes about 20 seconds on a typical laptop. Scroll to the end and compare the last printed lines with the lines in the step "What the notebook writes and what you must see" below. To keep the results, save the notebook (menu File > Save Notebook). To stop JupyterLab, choose the menu File > Shut Down, or press Ctrl+C twice in the terminal.

Step 6. Or run the notebook without a browser (headless).

In the repository folder, with the environment active, run:

Windows, macOS and Linux:

```
cd Revision/textbook/notebooks
jupyter nbconvert --to notebook --execute --inplace 17b_conserved_sources.ipynb
```

This runs every cell from the top to the bottom and saves the results into the notebook file. A failed check stops it with an error message that contains AssertionError and the name of the check. If the command ends with a line that starts with ‘[NbConvertApp] Writing‘ and shows no error, every check passed; open the notebook with ‘jupyter lab 17b_conserved_sources.ipynb‘ (in the same folder, without running the cells again) to read the printed lines and see the figures.

Step 7. What the notebook writes and what you must see.

The notebook writes (or overwrites) these files:

- ‘Revision/textbook/figures/17b.captions.json‘
- ‘Revision/textbook/figures/17b_1_eight_gammas.png‘
- ‘Revision/textbook/figures/17b_2_slope_identity.png‘
- ‘Revision/textbook/figures/17b_3_difference_order.png‘
- ‘Revision/textbook/figures/17b_4_brane_and_mean.png‘
- ‘Revision/textbook/figures/17b_5_energy_exchange.png‘
- ‘Revision/textbook/figures/17b_6_first_integral.png‘

It changes no other file of the repository; running it headless or saving it in JupyterLab also rewrites the notebook file itself. It does not use the internet while it runs. The files it writes are the same files that are stored in the repository (on another computer a figure may differ in a few bytes, which is harmless). To get the stored versions back, run this command in the repository folder (it also undoes every change you made yourself in the folder Revision/textbook):

Windows, macOS and Linux:

```
git checkout -- Revision/textbook
```

Every check of the notebook prints a line that starts with PASS. At the end of the notebook (the output of its last code cell) you must see exactly these lines:

```
    PASS every figure file of this notebook exists
    ALL 20 CHECKS PASSED (notebook 17b)
```

and the notebook must show 6 figures below the cells that draw them.

Step 8. If something goes wrong.

- "ModuleNotFoundError: No module named ..." in the notebook: JupyterLab was started without the environment. Stop it (menu File > Shut Down), do Step 4, and start it again. If the error remains, another Python installation has registered its own kernel called python3; with the environment active, run the following command and start JupyterLab again:

  ```
  python -m ipykernel install --user --name python3
  ```

- "FileNotFoundError: The repository folder was not found": the notebook was opened from a copy outside the repository. Open the file ‘Revision/textbook/notebooks/17b_conserved_sources.ipynb‘ inside the folder Dirac_claude.
- "fatal: destination path ’Dirac_claude’ already exists" in Step 3: the repository was downloaded before; skip the line with ‘git clone‘.
- Windows: "running scripts is disabled on this system": run the line with ‘Set-ExecutionPolicy‘ and then the activation line again. "py is not recognized": use ‘python‘ instead of ‘py -3‘; "python is not recognized": install Python again and tick "Add python.exe to PATH".
- Linux: "ensurepip is not available" when the environment is created: run ‘sudo apt install python3-venv‘ and repeat Step 3.
- "jupyter is not recognized" or "command not found: jupyter": the environment is not active; do Step 4. If the environment is active and the message stays, the programs jupyter-lab and jupyter-nbconvert are not in the folders where the terminal looks for programs (‘python -m jupyter‘ does not help then: it has to find the same programs). Start them through Python itself, in the folder of the notebook: the first command below does what ‘jupyter lab‘ does, the second what the headless command does:

  ```
  python -m jupyterlab 17b_conserved_sources.ipynb
  python -m nbconvert --execute --inplace 17b_conserved_sources.ipynb
  ```

- Windows: the headless run prints a RuntimeWarning that mentions the "Proactor event loop" and zmq: this is a message of the package pyzmq, not an error; the run continues normally.
- A red box with "Matplotlib is building the font cache; this may take a moment." in the first run after the installation: this is a message, not an error; the run continues and the message does not come again.
- An AssertionError names a check that failed: choose the menu Kernel > Restart Kernel and Run All Cells; if it fails again, install the packages again with the pip commands of Step 3, because a different package version can change the last digits of a result.
- "FileNotFoundError" naming gammas.json, a report or a profile file: the notebook reads the Revision records of the repository. Run it inside the folder Revision/textbook/notebooks of a complete copy of the repository made with git clone, not on a copy of the notebook file alone.
- the check of the sha256 fingerprint of gammas.json fails: the file was changed, for example by an editor or a tool that converted its line endings. Restore it with the command below, run in the repository folder.

```
    git checkout HEAD Revision/algebra/gammas.json
```

The first code cell below (the set-up cell) repeats these instructions as comments; then it imports the packages, finds the repository folder and defines the helpers ‘save_figure‘ (saves a figure and shows it), ‘check‘ (stops with an AssertionError when a check fails, prints a PASS line when it passes), ‘report‘ (prints a key number as a RESULT line) and ‘all_checks_passed‘ (prints the last line).

In [1]:

```
# HOW TO RUN NOTEBOOK 17b (the complete instructions)
#
# STEP 1. WHAT THIS NOTEBOOK DOES AND WHAT IT NEEDS.
#
# Notebook 17b (The conservation laws and the source conditions: why the Kohn-Sham states
# fail) is the file Revision/textbook/notebooks/17b_conserved_sources.ipynb of the
# repository Dirac_claude. It checks that the Kohn-Sham source of chapter 17 rests on the
# eight real 16 x 16 gamma matrices of the author (the very file the Rust solver read),
# derives with sympy the conservation law of a source in the author's metric, in the
# coordinate x0 and in the hidden coordinate y, and compares it with the Revision
# records. It proves that for a conserved source the violation p3 + p_t - 2 p0 of
# condition C2 equals the slope of p0 along y divided by 3H, and that the time derivative
# of the constraint is 3 a4' times the evolution equation, so that the linear member
# needs p3 = p_t. It then tests these identities on the 75 recorded Kohn-Sham ground
# states: point by point with fourth-order differences and a convergence study,
# integrated with the brane and tip values, and along the deflating history with
# Simpson's rule. The Kohn-Sham states obey the conservation law of the hidden direction
# at every point and the energy law of the time direction for the total energy of the
# patch (not point by point), and still fail the source conditions. Finally it averages
# the source over the hidden direction and integrates the averaged a4 equations of
# Einstein gravity with their first integral, an approximation whose numbers it checks
# against the Revision record. Six teaching plots. It needs a computer with Windows 11,
# macOS or Linux, an internet connection for the installation, the program Git, and
# Python 3.12 or newer (the notebooks were built with Python 3.14.5) with these packages
# at exactly these versions: numpy 2.4.6, sympy 1.14.0, mpmath 1.3.0, matplotlib 3.11.0,
# jupyterlab 4.4.10, nbformat 5.10.4, nbclient 0.10.2, ipykernel 7.1.0 and nbconvert
# 7.16.6. The notebook itself imports numpy, sympy and matplotlib; the other packages run
# Jupyter, the program that shows and runs notebooks. It does not need Rust.
#
# STEP 2. INSTALL GIT AND PYTHON (ONCE PER COMPUTER).
#
# A terminal is the window in which you type commands: on Windows the app Windows
# PowerShell (or Terminal), on macOS the app Terminal (it runs the shell zsh), on Linux
# any terminal (it runs the shell bash). Type every command of this section into a
# terminal exactly as printed, one line at a time, and press Enter after each line.
#
# Windows: download Git from https://git-scm.com/download/win and install it with the
# default choices. Download Python from https://www.python.org/downloads/ and run the
# installer; in its first window tick the box "Add python.exe to PATH" before you click
# "Install Now".
#
# macOS: download Python from https://www.python.org/downloads/ and run the installer.
# Then open the app Terminal and run this command, which installs Git and the compiler
```

```
# tools:
#
# macOS (zsh):
#     xcode-select --install
#
# Linux (Debian or Ubuntu; other distributions have packages of the same names): run
# these two commands:
#
# Linux (bash):
#     sudo apt update
#     sudo apt install git python3 python3-venv
#
# Then close the terminal and open a NEW one (a terminal opened before the installation
# does not know the new programs), and check the version of Python; it must print 3.12 or
# a higher number:
#
# Windows (PowerShell):
#     py -3 --version
#
# macOS (zsh) and Linux (bash):
#     python3 --version
#
# If an older Linux prints a lower number (Ubuntu 22.04 has Python 3.10), install Python
# 3.12 with the following three commands, and in Step 3 type python3.12 instead of
# python3 in the command that creates the environment:
#
# Linux (bash), only when the version is too low:
#     sudo add-apt-repository ppa:deadsnakes/ppa
#     sudo apt update
#     sudo apt install python3.12 python3.12-venv
#
# STEP 3. GET THE REPOSITORY AND INSTALL THE PACKAGES (ONCE PER COMPUTER).
#
# The commands below download the repository (a few hundred megabytes; the folder then
# needs up to about 1 GB of disk space) into the folder Dirac_claude inside your home
# folder, create a private Python environment in the folder dirac-book-env inside your
# home folder (a private environment is a folder with its own copy of Python and of the
# packages, so that nothing else on your computer is changed), activate it (from then on
# the commands python and jupyter typed in this terminal are those of the environment,
# and the prompt starts with (dirac-book-env)), and install the packages at the pinned
# versions (this downloads about 90 MB and takes a few minutes; the environment takes
# about 400 MB of disk space). If you have done this step before, for this or for another
# notebook, skip it and go to Step 4; to get the newest version of the repository, run
# git pull in the repository folder after Step 4.
#
# Windows (PowerShell):
#     cd $HOME
#     git clone https://github.com/once-ere/Dirac_claude.git
#     py -3 -m venv "$HOME\dirac-book-env"
#     Set-ExecutionPolicy -ExecutionPolicy RemoteSigned -Scope Process -Force
#     & "$HOME\dirac-book-env\Scripts\Activate.ps1"
#     python -m pip install --upgrade pip
#     python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
#     python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
```

```
#     python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
#
# The line with Set-ExecutionPolicy allows PowerShell to run the activation script in
# this one window only; it changes nothing permanently.
#
# macOS (zsh):
#     cd ~
#     git clone https://github.com/once-ere/Dirac_claude.git
#     python3 -m venv ~/dirac-book-env
#     source ~/dirac-book-env/bin/activate
#     python -m pip install --upgrade pip
#     python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
#     python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
#     python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
#
# Linux (bash):
#     cd ~
#     git clone https://github.com/once-ere/Dirac_claude.git
#     python3 -m venv ~/dirac-book-env
#     source ~/dirac-book-env/bin/activate
#     python -m pip install --upgrade pip
#     python -m pip install numpy==2.4.6 sympy==1.14.0 mpmath==1.3.0 matplotlib==3.11.0
#     python -m pip install jupyterlab==4.4.10 nbformat==5.10.4 nbclient==0.10.2
#     python -m pip install ipykernel==7.1.0 nbconvert==7.16.6
#
# STEP 4. IN EVERY NEW TERMINAL: ACTIVATE THE ENVIRONMENT AND GO INTO THE REPOSITORY
# FOLDER.
#
# Every later step starts in the repository folder with the environment active. Run these
# lines whenever you open a new terminal (they do no harm if the environment is already
# active):
#
# Windows (PowerShell):
#     Set-ExecutionPolicy -ExecutionPolicy RemoteSigned -Scope Process -Force
#     & "$HOME\dirac-book-env\Scripts\Activate.ps1"
#     cd "$HOME\Dirac_claude"
#
# macOS (zsh) and Linux (bash):
#     source ~/dirac-book-env/bin/activate
#     cd ~/Dirac_claude
#
# STEP 5. RUN THE NOTEBOOK IN JUPYTERLAB.
#
# In the repository folder, with the environment active, run these two lines (the first
# one goes into the folder of the notebooks):
#
# Windows, macOS and Linux:
#     cd Revision/textbook/notebooks
#     jupyter lab 17b_conserved_sources.ipynb
#
# JupyterLab opens in your web browser and shows the notebook (if no browser window
# opens, copy the address that starts with http://localhost:8888/lab from the terminal
# into the address bar of your browser). The name at the top right of the notebook must
# read Python 3 (ipykernel). Choose the menu Run > Run All Cells. While a cell runs, the
```

```
# label to its left shows [*]; when it has finished, the label shows a number. The
# notebook has finished when the last code cell shows a number; this takes about 20
# seconds on a typical laptop. Scroll to the end and compare the last printed lines with
# the lines in the step "What the notebook writes and what you must see" below. To keep
# the results, save the notebook (menu File > Save Notebook). To stop JupyterLab, choose
# the menu File > Shut Down, or press Ctrl+C twice in the terminal.
#
# STEP 6. OR RUN THE NOTEBOOK WITHOUT A BROWSER (HEADLESS).
#
# In the repository folder, with the environment active, run:
#
# Windows, macOS and Linux:
#     cd Revision/textbook/notebooks
#     jupyter nbconvert --to notebook --execute --inplace 17b_conserved_sources.ipynb
#
# This runs every cell from the top to the bottom and saves the results into the notebook
# file. A failed check stops it with an error message that contains AssertionError and
# the name of the check. If the command ends with a line that starts with [NbConvertApp]
# Writing and shows no error, every check passed; open the notebook with jupyter lab
# 17b_conserved_sources.ipynb (in the same folder, without running the cells again) to
# read the printed lines and see the figures.
#
# STEP 7. WHAT THE NOTEBOOK WRITES AND WHAT YOU MUST SEE.
#
# The notebook writes (or overwrites) these files:
#
# - Revision/textbook/figures/17b.captions.json
# - Revision/textbook/figures/17b_1_eight_gammas.png
# - Revision/textbook/figures/17b_2_slope_identity.png
# - Revision/textbook/figures/17b_3_difference_order.png
# - Revision/textbook/figures/17b_4_brane_and_mean.png
# - Revision/textbook/figures/17b_5_energy_exchange.png
# - Revision/textbook/figures/17b_6_first_integral.png
#
# It changes no other file of the repository; running it headless or saving it in
# JupyterLab also rewrites the notebook file itself. It does not use the internet while
# it runs. The files it writes are the same files that are stored in the repository (on
# another computer a figure may differ in a few bytes, which is harmless). To get the
# stored versions back, run this command in the repository folder (it also undoes every
# change you made yourself in the folder Revision/textbook):
#
# Windows, macOS and Linux:
#     git checkout -- Revision/textbook
#
# Every check of the notebook prints a line that starts with PASS. At the end of the
# notebook (the output of its last code cell) you must see exactly these lines:
#
#     PASS every figure file of this notebook exists
#     ALL 20 CHECKS PASSED (notebook 17b)
#
# and the notebook must show 6 figures below the cells that draw them.
#
# STEP 8. IF SOMETHING GOES WRONG.
#
```

```
# - "ModuleNotFoundError: No module named ..." in the notebook: JupyterLab was started
#   without the environment. Stop it (menu File > Shut Down), do Step 4, and start it
#   again. If the error remains, another Python installation has registered its own
#   kernel called python3; with the environment active, run the following command and
#   start JupyterLab again:
#     python -m ipykernel install --user --name python3
# - "FileNotFoundError: The repository folder was not found": the notebook was opened
#   from a copy outside the repository. Open the file
#   Revision/textbook/notebooks/17b_conserved_sources.ipynb inside the folder
#   Dirac_claude.
# - "fatal: destination path 'Dirac_claude' already exists" in Step 3: the repository was
#   downloaded before; skip the line with git clone.
# - Windows: "running scripts is disabled on this system": run the line with
#   Set-ExecutionPolicy and then the activation line again. "py is not recognized": use
#   python instead of py -3; "python is not recognized": install Python again and tick
#   "Add python.exe to PATH".
# - Linux: "ensurepip is not available" when the environment is created: run sudo apt
#   install python3-venv and repeat Step 3.
# - "jupyter is not recognized" or "command not found: jupyter": the environment is not
#   active; do Step 4. If the environment is active and the message stays, the programs
#   jupyter-lab and jupyter-nbconvert are not in the folders where the terminal looks for
#   programs (python -m jupyter does not help then: it has to find the same programs).
#   Start them through Python itself, in the folder of the notebook: the first command
#   below does what jupyter lab does, the second what the headless command does:
#     python -m jupyterlab 17b_conserved_sources.ipynb
#     python -m nbconvert --execute --inplace 17b_conserved_sources.ipynb
# - Windows: the headless run prints a RuntimeWarning that mentions the "Proactor event
#   loop" and zmq: this is a message of the package pyzmq, not an error; the run
#   continues normally.
# - A red box with "Matplotlib is building the font cache; this may take a moment." in
#   the first run after the installation: this is a message, not an error; the run
#   continues and the message does not come again.
# - An AssertionError names a check that failed: choose the menu Kernel > Restart Kernel
#   and Run All Cells; if it fails again, install the packages again with the pip
#   commands of Step 3, because a different package version can change the last digits of
#   a result.
# - "FileNotFoundError" naming gammas.json, a report or a profile file: the notebook
#   reads the Revision records of the repository. Run it inside the folder
#   Revision/textbook/notebooks of a complete copy of the repository made with git clone,
#   not on a copy of the notebook file alone.
# - the check of the sha256 fingerprint of gammas.json fails: the file was changed, for
#   example by an editor or a tool that converted its line endings. Restore it with the
#   command below, run in the repository folder.
#     git checkout HEAD Revision/algebra/gammas.json
#
# ------------------------------------------------------------------------------------

## 3. The words used in this notebook

- **Coordinates** (the author's names): $x_1, x_2, x_3$ = ordinary 3-space,
  which inflates (scale factor $e^{a_4}\sin^{1/6}z$); $x_4$ = the time;
  $x_5, x_6, x_7$ = the three **extra times**, which **deflate exponentially**
  (scale factor $e^{-a_4}\sin^{1/6}z$, with $a_4$ increasing); $x_0$ = the hidden
  space direction, $z = 6Hx_0$ between $0$ and $\pi/2$.
- **Hidden coordinate** $y = \ln(\sin z)/(6H)$: another way to number the points
  of the hidden direction; $y = 0$ is the **brane** ($z = \pi/2$), $y = -3$ the
  **tip cutoff** of the computations. A **chart** is a choice of coordinates.
- **Gamma matrices** $\gamma^{(x_0)}, \dots, \gamma^{(x_7)}$: eight square tables
  of numbers with $\gamma^a\gamma^b + \gamma^b\gamma^a = 2\eta^{ab}\,1$ (the
  **Clifford relation**), $\eta = \mathrm{diag}(+1,+1,+1,+1,-1,-1,-1,-1)$. The
  author's are real $16 \times 16$ **signed permutation matrices**: each row and
  each column holds exactly one nonzero entry, $+1$ or $-1$.
- **sha256 fingerprint**: a 64-digit code computed from the bytes of a file; two
  files with the same fingerprint are, for all practical purposes, identical.
- **Energy-momentum tensor** $T^\mu{}_\nu$ (the **source**): here
  $T = \mathrm{diag}(p_3, p_3, p_3, -\rho, p_t, p_t, p_t, p_0)$ in the order
  $x_0, \dots, x_7$, with energy density $\rho$ and pressures $p_3$ (3-space),
  $p_t$ (extra times), $p_0$ (hidden direction); possibly mixed entries $q_{40}$
  (row $x_4$, column $x_0$) and $q_{04}$.
- **Christoffel symbols** $\Gamma^\lambda{}_{\mu\nu} = \tfrac12 g^{\lambda\kappa}
  (\partial_\mu g_{\kappa\nu} + \partial_\nu g_{\kappa\mu} -
  \partial_\kappa g_{\mu\nu})$: numbers built from the first derivatives of the
  metric that say how the coordinate directions turn from point to point.
- **Covariant divergence** $\nabla_\mu T^\mu{}_\nu = \partial_\mu T^\mu{}_\nu +
  \Gamma^\mu{}_{\mu\lambda}T^\lambda{}_\nu - \Gamma^\lambda{}_{\mu\nu}
  T^\mu{}_\lambda$ (sum over repeated indices): the curved-space version of "what
  flows out of a small box". The **conservation law** is
  $\nabla_\mu T^\mu{}_\nu = 0$ for every $\nu$.
- **Bianchi identity**: the left-hand sides of the Einstein-Lovelock equations
  have zero covariant divergence for EVERY metric; hence every source of the
  equations must be conserved.
- **Source conditions** (from the $a_4$ equations): **C1** no component of the
  source depends on $x_0$ and $q_{40} = q_{04} = 0$; **C2** $p_3 + p_t = 2p_0$;
  **C3** for the linear member $a_4 = AHx_4 + a_0$: $p_3 = p_t = p_0$ and a
  constant $\rho$. **Admissible source**: one that meets them.
- **Constraint** (the $x_4$ equation, no $a_4''$) and **evolution equation**
  ($a_4''\,F(a_4') = \kappa(p_3 - p_t)$) of the $a_4$ equations.
- **Finite difference** of fourth order: the slope of a tabulated function from
  five neighbouring values,
```

```
  $f'(y) \approx [-f(y+2h) + 8f(y+h) - 8f(y-h) + f(y-2h)]/(12h)$; its error falls
  like $h^4$ when the step $h$ shrinks (**order of accuracy** 4).
- **Simpson's rule**: the integral of a function over $[a, a+2h]$ is about
  $(h/3)[f(a) + 4f(a+h) + f(a+2h)]$; error like $h^4$.
- **Weighted mean**: $\int e^{6Hy}p_0\,dy / \int e^{6Hy}dy$, the average of
  $p_0$ over the proper volume.
- **Kohn-Sham state**, **slice** $a_{4,0}$, **history** $a_4 = AHx_4$ with
  $A = 1$, **prescribed background**, **test field**, **back-reaction**: as in
  Notebook 17a; a state name such as `N136_lamp2_a20` means $N = 136$,
  $\lambda = +\lambda_2$, $a_{4,0} = 2.0$.
- **Least squares**: the straight line through a set of points that makes the sum
  of the squared vertical distances of the points from the line as small as
  possible.
- **Weighted average over the hidden direction** $\bar X$ (also called the
  **moment** of $X$): the integral of $e^{6Hy}X$ over the patch divided by the
  integral of $e^{6Hy}$. A **moment equation** is a field equation multiplied by
  $e^{6Hy}$ and integrated over the patch.
- **First integral**: an equation with only first derivatives that every solution
  of a second-order equation obeys; here $a_4'^2$ as a function of $a_4$.
- **Cubic Hermite interpolation**: between two tabulated points, the cubic
  polynomial with the given values AND the given slopes at both ends.
- **Turning point**: the value of $a_4$ where $a_4'$ reaches $0$; there the
  deflation of the extra times halts.
- **Status labels**: PROVED (exact), COMPUTED (numerical, with its measured
  error), ASSUMED (including a stated approximation), OPEN. Units: $H = 1$,
  $m = 1$.
```

```
## 4. The physical and mathematical situation

The field equations of gravity, $\sum_k\alpha_kE_{(k)}{}^\mu{}_\nu +
\Lambda\delta^\mu_\nu = \kappa T^\mu{}_\nu$, have a left-hand side whose covariant
divergence vanishes identically (the Bianchi identity; the Revision record checks
it for all three Lovelock tensors of the author's metric). Taking the divergence
of both sides gives $\kappa\nabla_\mu T^\mu{}_\nu = 0$: a source must be
conserved. Conservation is therefore NECESSARY. This notebook shows that it is not
SUFFICIENT, and that it explains the failure of the Kohn-Sham states.

The Kohn-Sham states are computed in the prescribed background $a_4 = Hx_4$ (the
extra times deflate as $e^{-a_4}$, 3-space inflates as $e^{a_4}$). A field that
solves its own TIME-DEPENDENT field equation in a given metric has a conserved
energy-momentum tensor. The Kohn-Sham states are not such solutions: each one
solves the instantaneous problem of one slice (the stationary-slice ansatz). So
the Revision record proves less, and exactly this: the conservation law of the
hidden direction for every self-consistent state, at every point; and the
energy-change law of the time direction only INTEGRATED over the hidden
direction, for the instantaneous states followed with fixed occupations (they
carry no energy flux along $y$). The Rust solver checks both numerically. We will
see:

1. in the hidden direction, conservation reads
   $p_0' + 6Hp_0 = 3H(p_3 + p_t)$ (the prime is $d/dy$); hence the violation of
```

```
   C2 is $V = p_3 + p_t - 2p_0 = p_0'/(3H)$. For a conserved source without mixed
   entries, C2 and "$p_0$ does not depend on $x_0$" (part of C1) are the SAME
   condition. The Kohn-Sham $p_0$ changes by orders of magnitude along $y$, so C2
   must fail;
2. in the time direction, conservation reads $\rho' = -3a_4'(p_3 - p_t)$ (the
   prime is $d/dx_4$): energy flows between the source and the expanding and
   deflating directions unless $p_3 = p_t$. The Kohn-Sham gas has
   $p_3 > 0 = p_t$ (at $\lambda = 0$), so its energy must change along the
   history, which C3 forbids. For the Kohn-Sham states this law holds for the
   energy of the whole patch but fails point by point (section 12).
```

Text cell:

```
## 5. The Revision records and the helpers that read them

The next cell imports the packages and names the Revision records used below. It
defines four helpers: ‘read_json‘ reads a JSON file of the repository,
‘record_entry‘ finds a check by its name in a Revision report, ‘reproduces‘ is
a check that passes only when this notebook's own result holds AND the named
checks of the report have the verdict PASS, and ‘tex_number‘ writes a number in
powers of ten for the captions. Then it counts the checks of the seven reports and
requires that all of them passed.
```

## 6. The eight real $16 \times 16$ gamma matrices behind the Kohn-Sham source

dirac16complex is a 16-component spinor field, and its field equation, its
Lagrangian and its energy-momentum tensor are written with the author's eight
real $16 \times 16$ gamma matrices. The Kohn-Sham solver reduces the 16-component
equation to $2 \times 2$ blocks; the solver's own check `block_reduction_numeric`
confirms that its blocks are exactly the 16-component Hamiltonian written in
another basis. The next cell reads the matrices from the Revision record
`gammas.json` and checks: there are eight; each is $16 \times 16$; every entry is
a JSON integer (so the matrices are REAL) equal to $-1$, $0$ or $+1$; each is a
signed permutation matrix.
```

In [3]:

```
gamma_record = read_json(GAMMAS)
entries = [v for matrix in gamma_record["gamma"] for row in matrix for v in row]
real_integers = all(isinstance(v, int) for v in entries)  # no complex entries
gamma = [np.array(matrix, dtype=float) for matrix in gamma_record["gamma"]]
eta = np.array(gamma_record["eta"], dtype=float)  # +1 or -1 for x0, ..., x7
shapes = sorted({matrix.shape for matrix in gamma})  # should be one shape only
values = sorted({int(v) for v in entries})  # the entries that occur
one_per_line = all(np.all(np.count_nonzero(matrix, axis=0) == 1)
                   and np.all(np.count_nonzero(matrix, axis=1) == 1)
                   for matrix in gamma)  # one nonzero entry per row and column
report("number of gamma matrices", len(gamma))
report("their shapes", shapes)
report("the entries that occur", values)
report("eta in the order x0, ..., x7", [int(v) for v in eta])
reproduces(len(gamma) == 8 and shapes == [(16, 16)] and real_integers
           and values == [-1, 0, 1] and one_per_line,
           "eight real 16 x 16 signed permutation matrices",
           ALGEBRA, ["reality_signed_permutations"])
```

Out [3]:

```
RESULT number of gamma matrices = 8
RESULT their shapes = [(16, 16)]
RESULT the entries that occur = [-1, 0, 1]
RESULT eta in the order x0, ..., x7 = [1, 1, 1, 1, -1, -1, -1, -1]
PASS eight real 16 x 16 signed permutation matrices
     reproduces Revision/algebra/reports/python-algebra.json, check
    reality_signed_permutations
```

Text cell:

```
The next cell checks the Clifford relation
$\gamma^a\gamma^b + \gamma^b\gamma^a = 2\eta^{ab}\,1$ for all $8 \times 8 = 64$
ordered pairs $(a, b)$ (the products of integer matrices are exact in floating
point), and it computes the sha256 fingerprint of the file ‘gammas.json‘. The Rust
solver printed the first 16 digits of the fingerprint of the file it read into
its check ‘gamma_fixture_numeric‘; equal digits show that the Kohn-Sham states
were computed with exactly these matrices.
```

## 7. The hidden coordinate $y$

The author's metric has $g_{00} = \cot^2 z$ with $z = 6Hx_0$, and the warp factor
$\sin^{1/3}z$ in front of the six directions $x_1, x_2, x_3, x_5, x_6, x_7$. The
Kohn-Sham computations use $y = \ln(\sin z)/(6H)$ instead of $x_0$. The next cell
derives, step by step with sympy:

1. $dy/dx_0 = \cot z$ (the chain rule: $d\ln(\sin z)/dz = \cot z$ and
   $dz/dx_0 = 6H$);
2. $g_{yy} = g_{00}\,(dx_0/dy)^2 = \cot^2 z/\cot^2 z = 1$: $y$ measures proper
   length along the hidden direction;
3. $\sin z = e^{6Hy}$, so the warp factor is $\sin^{1/3}z = e^{2Hy}$;
4. $\sqrt{|\det g|} = \cos z$ in the $x_0$ chart and $e^{6Hy}$ in the $y$ chart
   (the factors $e^{\pm 2a_4}$ of 3-space and of the extra times cancel in the
   determinant: the 7-volume does not change while 3-space inflates and the
   extra times deflate).

To let sympy simplify powers safely, $\sin z$ and $\cos z$ are written as
positive symbols $s$ and $c$ (both are positive for $0 < z < \pi/2$).
```

## 8. The conservation law of a source in the author's metric

The next cell defines two helpers that work for any diagonal metric:
‘christoffel‘ computes all $8 \times 8 \times 8 = 512$ Christoffel symbols with
the formula of section 3, and ‘divergence‘ computes the eight components
$\nabla_\mu T^\mu{}_\nu$, $\nu = 1, \dots, 8$, of the covariant divergence of a
table $T^\mu{}_\nu$ (stored as ‘T[mu, nu]‘). It then builds the author's metric in
the $x_0$ chart with a general function $a_4(x_4)$, and the most general source
the $a_4$ record allows: $\rho, p_3, p_t, p_0, q_{40}, q_{04}$, each a function of
$x_4$ and $x_0$. Finally it prints the eight components of the divergence, written
in the record's notation: ‘ad1‘ is $a_4'$, ‘d4rho‘ is $\partial\rho/\partial x_4$,
‘d0p0‘ is $\partial p_0/\partial x_0$, ‘cc‘ is $\cot z$, and so on (the helper
‘readable‘ collects the terms of each source quantity and simplifies the factor in
front of it with $\sin 2z = 2\sin z\cos z$ and $\tan z = \sin z/\cos z$).

## 9. The conservation law in the coordinate $y$, and what it does to C2

The Kohn-Sham states have $q_{40} = q_{04} = 0$ (their mixed component vanishes
for every eigen-orbital) and depend on $y$. In the $y$ chart the author's metric
```

```
is, by section 7,
$e^{2Hy}[e^{2a_4}(dx_1^2 + dx_2^2 + dx_3^2) - e^{-2a_4}(dx_5^2 + dx_6^2 +
dx_7^2)] - dx_4^2 + dy^2$. The next cell computes the covariant divergence of a
diagonal source $T(x_4, y)$ in this chart with the same helper and checks the two
surviving components against the formulas

$$\nabla_\mu T^\mu{}_{x_4} = -\partial_4\rho - 3a_4'(p_3 - p_t), \qquad
\nabla_\mu T^\mu{}_y = p_0' + 6Hp_0 - 3H(p_3 + p_t)$$

of the Kohn-Sham theory record (the prime on $p_0$ is $\partial/\partial y$). It
prints the components with short names: `ad1` is $a_4'$, `d4rho` is
$\partial\rho/\partial x_4$ and `dyp0` is $\partial p_0/\partial y$.
```

In [9]:

```

```

Text cell:

```
Now the key step. Solve the $y$ law for $p_3$:
$p_3 = (p_0' + 6Hp_0)/(3H) - p_t$. Put this into the violation of C2:

$$V = p_3 + p_t - 2p_0 = \frac{p_0' + 6Hp_0}{3H} - 2p_0 = \frac{p_0'}{3H}.$$

The first equality is the definition of $V$; the second replaces $p_3 + p_t$ by
its value from the conservation law; the third cancels $6Hp_0/(3H) = 2p_0$
against $-2p_0$. So, for EVERY conserved diagonal source: **C2 holds at a point
exactly when $p_0$ is flat there.** C2 is not an extra demand on a conserved
source; it is the $p_0$ part of C1. The next cell repeats the algebra with
sympy.
```

In [10]:

## 10. Testing $V = p_0'/(3H)$ on the recorded Kohn-Sham states

The next cell reads the 75 profile files of the Kohn-Sham record (151 points
$y = -3, -2.98, \dots, 0$; columns `rho`, `p3`, `p_t`, `p0` among others), the
table of integrals and the parameters. It defines `slope`, the fourth-order
difference of section 3 with the step $s \cdot h$ ($h = 0.02$, $s = 1, 2, \dots$),
evaluated at the inner points (two points at each end have no neighbours on one
side). For every state with a nonzero tensor it compares $V$ with $p_0'/(3H)$ and
divides the largest difference by max|T| (the largest absolute value of $\rho$,
$p_3$, $p_t$, $p_0$ of the state).
```

```
## 11. The integrated form, and why the integrated ratio of C2 is not 1

Multiply the $y$ law by $e^{6Hy}$: since $(e^{6Hy}p_0)' = e^{6Hy}(p_0' + 6Hp_0)$
(product rule), the law becomes $(e^{6Hy}p_0)' = 3He^{6Hy}(p_3 + p_t)$. Integrate
from the tip $y = -L$ to the brane $y = 0$ (fundamental theorem of calculus) and
multiply by $2\,\mathrm{Vol}_7$ (the volume factor of the record's integrals):

$$2\,\mathrm{Vol}_7\left[p_0(0) - e^{-6HL}p_0(-L)\right] =
3H\left(\textstyle\int p_3 + \int p_t\right),$$

where $\int X$ means $2\,\mathrm{Vol}_7\int_{-L}^{0}e^{6Hy}X\,dy$, the column
`int_X` of the record's table. The next cell checks this with the table's brane
values, tip values and integrals for all 70 nonzero states (relative difference
of the two sides, divided by the right side). The table also has a column
`ycons_integrated_rel`: the solver's own relative difference of the same two
sides, computed from its unrounded numbers and divided by the largest of the terms
involved (not by the right side alone), so it is a close cousin of our number,
not the same number by definition; the cell checks that its largest value is the
one printed in the solver's check
`emt_y_conservation_integrated` (two mirror states, $\lambda = \pm\lambda_2$ with
$N = 8$, share this largest value; the record names one of them). Our
differences, computed from numbers printed with 16 digits, are of the same tiny
size, about $10^{-11}$.
```

Text cell:

```
Notebook 17a found that the integrated ratio $R = (\int p_3 + \int p_t)/(2\int
p_0)$ lies between about $0.1$ and $0.4$ instead of $1$. The integrated law
explains this number. Divide it by $2\int p_0$ and write $\int p_0 =
2\,\mathrm{Vol}_7\,\bar p_0\,(1 - e^{-6HL})/(6H)$, where $\bar p_0$ is the
weighted mean of $p_0$ (because $\int_{-L}^0 e^{6Hy}dy = (1 - e^{-6HL})/(6H)$):

$$R = \frac{b_0}{\bar p_0}, \qquad b_0 = \frac{p_0(0) - e^{-6HL}p_0(-L)}
{1 - e^{-6HL}}.$$

We call $b_0$ the **boundary value** of $p_0$: the brane value with the small tip
term. So the averaged C2 asks that the boundary value of $p_0$ equal its mean:
true for a flat $p_0$, false for the Kohn-Sham states. Is the tip term negligible,
so that $b_0 \approx p_0(0)$? The weight $e^{-6HL} = e^{-18}$ is tiny, but near the
tip $|p_0|$ is enormous. The next cell computes $R$ both ways for every nonzero
state, checks the record's closest value, and measures the share of $R$ that the
tip term supplies. It also measures, from the profiles, which part of the weighted
mean of $p_0$ comes from the last unit before the brane, $-1 \le y \le 0$.

## 12. The time direction: energy exchange and condition C3

The $x_4$ law of section 9 for a source that does not depend on $x_0$ reads
$\rho' = -3a_4'(p_3 - p_t)$. In words: when 3-space inflates ($a_4' > 0$) a
3-space pressure $p_3$ takes energy out of the source, and when the extra times
deflate an extra-time pressure $p_t$ puts energy in. For the linear member
$a_4' = AH \neq 0$, so a constant $\rho$ (part of C3) holds exactly when
$p_3 = p_t$ (another part of C3).

The $a_4$ equations know this. Write the constraint as
$\mathcal C = \sum_k\alpha_kE_{(k)}{}^{x_4}{}_{x_4} + \Lambda + \kappa\rho = 0$
and the evolution equation as $\mathcal E = a_4''F - \kappa(p_3 - p_t) = 0$. The
left-hand side of $\mathcal C$ depends on $x_4$ only through $a_4'$, so by the
chain rule $d\mathcal C/dx_4 = (\partial\mathcal C/\partial a_4')\,a_4'' +
\kappa\rho'$. The next cell inserts the record's Lovelock components and $F$,
uses $\rho' = -3a_4'(p_3 - p_t)$, and checks
$d\mathcal C/dx_4 = 3a_4'\,\mathcal E$ for all couplings $\alpha_1, \alpha_2,
\alpha_3$. Along the linear member ($a_4'' = 0$) this gives
$d\mathcal C/dx_4 = -3\kappa AH(p_3 - p_t)$: the constraint can hold at all
times only if $p_3 = p_t$.
```

```
For the Kohn-Sham gas only the integrated version of the $x_4$ law is recorded
(the cell after the next two shows why: point by point it fails):
$dE/da_{4,0} = -3\left(\int p_3 - \int p_t\right)$ with the total energy
$E = \int\rho$ (the Rust solver checks it with tiny steps of $a_4$). The recorded
slices are $0.5$ apart, so we can test it with Simpson's rule over the whole
history: $E(2) - E(0)$ must equal the integral of $-3(\int p_3 - \int p_t)$ from
$0$ to $2$. This is fair only if each state is followed continuously from slice
to slice (no level crosses the Fermi level); the record of the history lists no
such crossing. The next cell does this for all 15 series (three particle numbers,
five couplings).
```

## 13. The equations averaged over the hidden direction (an approximation)

No recorded ground state meets C1, so the $a_4$ equations cannot hold point by point
with the Kohn-Sham source. The Revision record in the folder
‘Revision/field_equations_a4/ks_source‘ asks the next weaker question: multiply
every field equation by the volume weight $e^{6Hy}$ and integrate it over the
patch. Because the left-hand sides do not depend on $y$, each one becomes the
same equation with the source replaced by its weighted average $\bar X$ (its
**moment**). These moment equations are NECESSARY conditions: every exact
solution obeys them. The next cell computes the averages
$\bar X = \int X / (2\,\mathrm{Vol}_7 W)$, $W = (1 - e^{-6HL})/(6H)$, of every
state from the record’s integrals, compares $\bar\rho$ with the record’s table of
averages, and evaluates the averaged C2 (the $x_1 + x_5 - 2x_0$ moment) through
its relative defect
$|\bar p_3 + \bar p_t - 2\bar p_0|/(|\bar p_3| + |\bar p_t| + 2|\bar p_0|)$,
which is $0$ when the averaged C2 holds.
```

In [21]:

```
MOMENTS = "Revision/field_equations_a4/ks_source/results/ks-source-moments.csv"

Text cell:

```
Which moment equations can hold together? The Revision record proves (checks
‘A4_constraint_propagation_with_averaged_source‘, ‘C2_averaged_energy_relation‘
and ‘C3_x0_moment_inconsistent_with_history‘) that the $x_4$ moment (the
constraint) and the $x_1 - x_5$ moment (the evolution equation) are consistent,
because the averages obey $d\bar\rho/da_4 = -3(\bar p_3 - \bar p_t)$; every set
that contains the $x_0$ moment is not. Keeping the consistent pair and dropping
the $x_0$ and $x_1 + x_5 - 2x_0$ moments is an APPROXIMATION; its error is the
dropped residuals, which the record finds to be of order 1. In Einstein gravity
the constraint is $3a_4'^2 + 21H^2 + \Lambda = -\kappa\bar\rho(a_4)$. At $a_4 = 0$
with the initial rate $a_4'(0) = H$ it fixes $\Lambda = -24H^2 - \sigma_0H^2$,
where $\sigma_0 = \kappa\bar\rho(0)/H^2$ is the source strength; subtracting the
two gives the **first integral**

$$\left(\frac{a_4'}{H}\right)^2 = 1 + \frac{\sigma_0}{3}\left(1 -
\frac{\bar\rho(a_4)}{\bar\rho(0)}\right).$$

The next cell evaluates it for the series $N = 136$, $\lambda = 0$: at the slice
$a_4 = 2$ for $\sigma_0 = 10, 1, -1$; and between the slices with the cubic
Hermite interpolant of $\bar\rho$ whose slopes are the exact
$-3(\bar p_3 - \bar p_t)$, to find by bisection the turning point where $a_4'$
reaches $0$ for $\sigma_0 = -10$ and for $\Lambda = 0$ ($\sigma_0 = -24$). It
compares every number with the record's table of integrated cases.
```

## 14. The last check
```

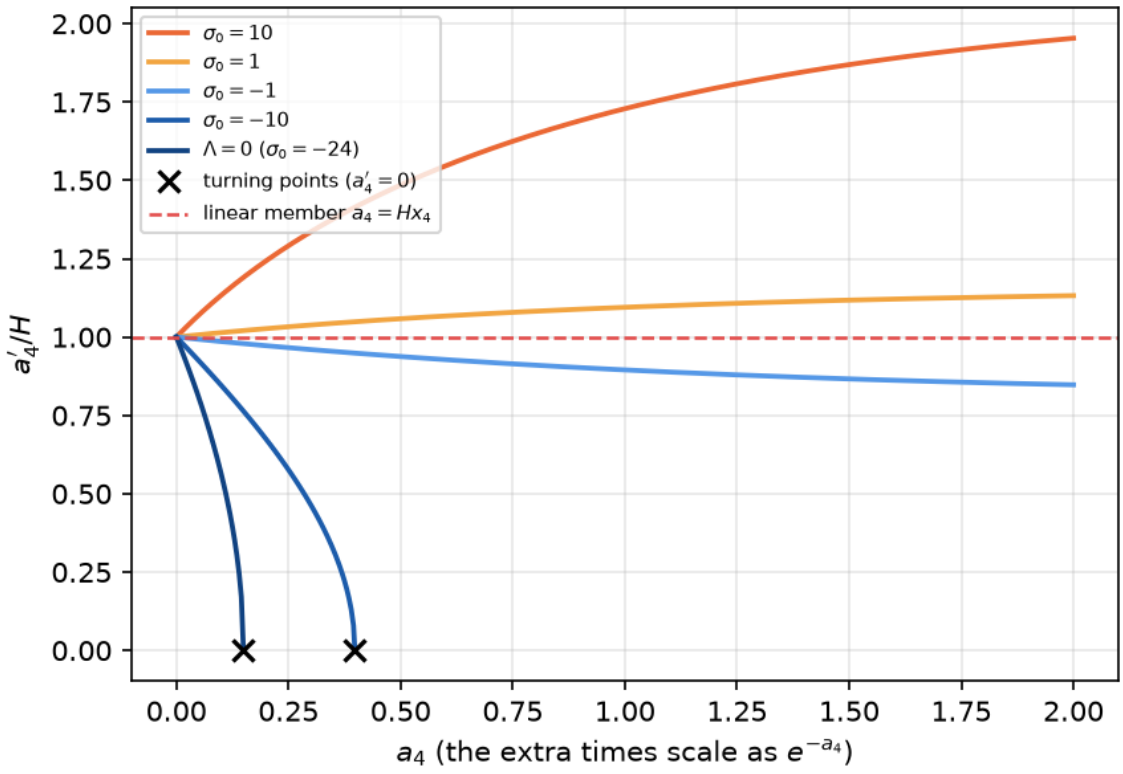

Figure 471: The rate a_4'/H of the deflation of the extra times against a_4 (pure numbers), from the first integral of the averaged a_4 equations of Einstein gravity with the Kohn-Sham source $N = 136$, $\lambda = 0$ (an APPROXIMATION: the x_0 moments are dropped), initial rate $a_4'(0) = H$, for the source strengths $\sigma_0 = \kappa\bar{\rho}(0)/H^2 = 10, 1, -1, -10$ and for $\Lambda = 0$ ($\sigma_0 = -24$). The dashed line is the constant rate of the history $a_4 = Hx_4$. A positive σ_0 speeds the deflation up ($a_4'/H = 1.954$ and 1.132 at $a_4 = 2$), a negative one slows it down (0.848 for $\sigma_0 = -1$); for $\sigma_0 = -10$ and for $\Lambda = 0$ it halts at $a_4 = 0.398$ and 0.150 (crosses). The source does not create the deflation: the initial rate is chosen. (Notebook 17b, figure 6.)

```
The last cell checks that the six figure files exist in the folder
Revision/textbook/figures and prints the number of checks that passed.
```

```
## 15. What this notebook showed

- COMPUTED and exact: the Kohn-Sham source rests on the author's eight REAL
  $16 \times 16$ gamma matrices (signed permutation matrices with the Clifford
  relation for all 64 pairs); the Rust solver read exactly this file (equal sha256
  digits).
- PROVED (sympy, equal to the $a_4$ record and to the Kohn-Sham theory record):
  in the author's metric a diagonal source is conserved when
  $\rho' = -3a_4'(p_3 - p_t)$ (time direction) and
  $p_0' + 6Hp_0 = 3H(p_3 + p_t)$ (hidden direction, coordinate $y$).
- PROVED: for a conserved source the violation of C2 is
  $p_3 + p_t - 2p_0 = p_0'(y)/(3H)$, so C2 is the statement "$p_0$ is flat"; and
  $d\mathcal C/dx_4 = 3a_4'\,\mathcal E$, so the linear member needs $p_3 = p_t$
  and a constant $\rho$.
- COMPUTED (the 75 recorded ground states): the Kohn-Sham states obey the conservation
  law of the hidden direction point by point (to about $10^{-4}$ of max|T| with
  fourth-order differences of step 0.02, the error falling with the fourth power
  of the step) and integrated over the patch (to about $10^{-11}$). The energy
  law of the time direction holds for the energy of the whole patch along the
  history (Simpson's rule, to about $2 \times 10^{-4}$), but NOT point by point:
  at the tip its two sides even have opposite signs. The instantaneous states
  carry no energy flux along $y$; a genuinely time-dependent state would need one
  ($q_{04} \neq 0$), and C1 forbids it.
- Hence the Kohn-Sham source is NOT ADMISSIBLE: its $p_0$ is far from flat (so
  C1 and C2 fail together) and its $p_3 > p_t$ makes its energy change along the
  history (so C3 fails). Conservation is necessary for a source of the $a_4$
  equations, not sufficient. The history $a_4 = Hx_4$ remains a PRESCRIBED
  BACKGROUND (ASSUMED), and the Kohn-Sham gas a test field without
  back-reaction.
- COMPUTED within an ASSUMED approximation (the Revision record `ks_source`,
  reproduced): averaged over the hidden direction, C2 still fails by a defect of
```

```
  order 1. Keeping only the consistent pair of moment equations (constraint and
  evolution) gives the first integral; in Einstein gravity the Kohn-Sham source
  changes a deflation that is
  already there by a bounded amount, and with $\Lambda = 0$ it halts it at
  $a_4 \approx 0.15$. It does not start or select the exponential deflation of
  the extra times: the initial rate is chosen.
- NOT shown (OPEN): what metric the Kohn-Sham gas would produce with
  back-reaction; whether any state of dirac16complex is an admissible source of
  the author's metric.
```

17.21 Line-by-line walk-through of Notebook 17b

The notebook has 24 code cells, In [1] to In [24]. As in Section 17.11, every line or small group of lines is quoted and explained, and each figure is described after the cell that draws it.

In [1], the set-up cell. It is the set-up cell of Notebook 17a, word for word, except for two things: the comment lines at the top hold the run instructions of Notebook 17b (Section 17.19), and the line `NOTEBOOK_ID = "17b"` names this notebook. Every line is explained in Section 17.11 under In [1]. The cell prints its one line, Set-up of notebook 17b complete: repository folder found, helpers defined.

In [2], the Revision records and the helpers.

```
import csv  # reads tables stored as CSV files (comma-separated values)
import hashlib  # computes the sha256 fingerprint of a file

import numpy as np  # arrays of numbers
import sympy as sp  # exact algebra with symbols
```

As in Notebook 17a, plus `hashlib`, a module of Python that computes fingerprints of data (In [4]).

```
GAMMAS = "Revision/algebra/gammas.json"  # the eight real 16 x 16 gammas
ALGEBRA = "Revision/algebra/reports/python-algebra.json"  # their checks
EQUATIONS = "Revision/field_equations_a4/a4-equations.json"  # the a4 equations
PY_A4 = "Revision/field_equations_a4/reports/python-a4-report.json"  # sympy
WL_A4 = "Revision/field_equations_a4/reports/wolfram-a4-report.json"  # Wolfram
SOURCE_REPORT = "Revision/field_equations_a4/reports/ks-source-conditions.json"
KS_SOURCE = "Revision/field_equations_a4/ks_source/reports/ks-source-a4.json"
KS_THEORY = "Revision/kohn_sham/ks-theory.json"  # the Kohn-Sham theory record
KS_PY = "Revision/kohn_sham/reports/ks-theory-python.json"  # its sympy checks
KS_RUST = "Revision/kohn_sham/reports/ks-rust-solver.json"  # the solver checks
GROUND = "Revision/kohn_sham/results/ground"  # the 75 Kohn-Sham ground states
```

Eleven names for the Revision records used below: the author's gamma matrices and the report of their checks; the record of the a_4 equations and its two reports; the record on the Kohn-Sham source conditions; the report of the a_4 equations with the Kohn-Sham source (Section 17.17); the Kohn-Sham theory record, its sympy report and the report of the Rust solver; and the folder of the recorded states.

```
def read_json(relative):
    """Read a JSON file of the repository (a Revision record)."""
    return json.loads(repository_file(relative).read_text(encoding="utf-8"))

def record_entry(report_file, name):
    """The entry {name, verdict, detail} of a check of a report, None if absent."""
    for entry in read_json(report_file)["checks"]:
        if entry["name"] == name:
            return entry
    return None

def reproduces(condition, name, report_file, record_names):
    """A check that also requires the named checks of the report to be PASS."""
    found = all((record_entry(report_file, n) or {}).get("verdict", "").upper()
                == "PASS" for n in record_names)  # some reports write "pass"
    names_text = ", ".join(record_names)  # the check names, separated by commas
    check(condition and found, name, record=f"{report_file}, check {names_text}")

def tex_number(value, digits=2):
    """A number for a caption in powers of ten: 0.0123 -> 1.2 \\times 10^{-2}."""
    mantissa, exponent = f"{value:.{digits - 1}e}".split("e")
    return f"{mantissa} \\times 10^{{{int(exponent)}}}"
```

The four helpers of Notebook 17a (Section 17.11, In [2]), with one change in `reproduces`: `.get("verdict", "")` returns an empty string when an entry has no verdict, and `.upper()` turns the verdict into capital letters, because the report of the algebra writes its verdicts as `pass` while the other reports write `PASS`.

```
REPORTS = [ALGEBRA, PY_A4, WL_A4, SOURCE_REPORT, KS_SOURCE, KS_PY, KS_RUST]
every_pass = True
for report_file in REPORTS:
    verdicts = [entry["verdict"].upper()
                for entry in read_json(report_file)["checks"]]
    passed = verdicts.count("PASS")  # how many checks of this report passed
    every_pass = every_pass and passed == len(verdicts)
    report(report_file.split("/")[-1], f"{passed} of {len(verdicts)} checks PASS")
check(every_pass, "every check of the seven Revision reports used here is PASS")
```

For each of the seven reports the cell collects the verdicts, counts the PASS among them (`.count`), keeps `every_pass` true only if all passed, and prints the file name (`split("/")[-1]`, the part after the last slash) with the count. Output: seven RESULT lines, one per report, each of the form "name of the report = n of n checks PASS", and the line PASS every check of the seven Revision reports used here is PASS. The numbers n are the numbers of checks that the reports held when the notebook was executed; they are printed in the notebook text above. The notebook does not require particular counts, because a report may gain checks when the Revision record is extended: the check asks only that every check of every report passes.

In [3], the eight gamma matrices are real signed permutation matrices.

```
gamma_record = read_json(GAMMAS)
entries = [v for matrix in gamma_record["gamma"] for row in matrix for v in row]
real_integers = all(isinstance(v, int) for v in entries)  # no complex entries
gamma = [np.array(matrix, dtype=float) for matrix in gamma_record["gamma"]]
eta = np.array(gamma_record["eta"], dtype=float)  # +1 or -1 for x0, ..., x7
```

The record `gammas.json` stores the eight matrices as lists of rows of numbers. The list comprehension with three `for` parts walks through every matrix, every row of it and every entry of the row, and collects all $8 \times 16 \times 16 = 2048$ entries. `isinstance(v, int)` is true when an entry is a whole number; a complex entry would be stored differently, so `real_integers` confirms that the matrices are REAL. Then each matrix becomes a numpy array of decimal numbers (`dtype=float`), and `eta` holds the eight signs of the frame metric.

```
shapes = sorted({matrix.shape for matrix in gamma})  # should be one shape only
values = sorted({int(v) for v in entries})  # the entries that occur
one_per_line = all(np.all(np.count_nonzero(matrix, axis=0) == 1)
                   and np.all(np.count_nonzero(matrix, axis=1) == 1)
                   for matrix in gamma)  # one nonzero entry per row and column
```

`matrix.shape` is the pair (rows, columns); a set keeps each different shape once. `values` is the sorted set of the different entries. `np.count_nonzero(matrix, axis=0)` counts the nonzero entries of every column and `axis=1` of every row; `one_per_line` is true when every column and every row of every matrix holds exactly one nonzero entry: then each matrix is a **signed permutation matrix**, which moves the 16 components of a spinor into a new order and changes some of their signs.

```
report("number of gamma matrices", len(gamma))
report("their shapes", shapes)
report("the entries that occur", values)
report("eta in the order x0, ..., x7", [int(v) for v in eta])
reproduces(len(gamma) == 8 and shapes == [(16, 16)] and real_integers
           and values == [-1, 0, 1] and one_per_line,
           "eight real 16 x 16 signed permutation matrices",
           ALGEBRA, ["reality_signed_permutations"])
```

Output: 8 matrices, the single shape (16, 16), the entries -1, 0, 1, $\eta = (1,1,1,1,-1,-1,-1,-1)$ in the order $x_0, \ldots, x_7$, and the PASS line, reproducing the algebra report's check `reality_signed_permutations`.

In [4], the Clifford relation and the fingerprint of the file.

```
identity16 = np.eye(16)  # the 16 x 16 unit matrix
deviation = 0.0  # the largest deviation from the Clifford relation
for a in range(8):
    for b in range(8):
        anticommutator = gamma[a] @ gamma[b] + gamma[b] @ gamma[a]
        target = 2.0 * eta[a] * identity16 if a == b else 0.0 * identity16
        deviation = max(deviation, float(np.max(np.abs(anticommutator - target))))
report("largest deviation from the Clifford relation, 64 pairs", deviation)
reproduces(deviation == 0.0, "the Clifford relation holds exactly for all 64 pairs",
           ALGEBRA, ["clifford_relation"])
```

`np.eye(16)` is the unit matrix. The two loops visit all $8 \times 8 = 64$ ordered pairs (a, b); `@` is matrix multiplication. The **anticommutator** $\gamma^a\gamma^b + \gamma^b\gamma^a$ is compared with $2\eta^{aa}$ times the unit matrix when $a = b$ and with the zero matrix otherwise, and `deviation` keeps the largest difference of any entry. Products and sums of matrices of whole numbers are exact in the computer, so the deviation must be exactly 0. Output: RESULT ... = 0.0 and the PASS line (algebra report, check `clifford_relation`).

```
fingerprint = hashlib.sha256(repository_file(GAMMAS).read_bytes()).hexdigest()
report("sha256 of gammas.json, first 16 digits", fingerprint[:16])
solver_detail = record_entry(KS_RUST, "gamma_fixture_numeric")["detail"]
reproduces(f"(sha256 {fingerprint[:16]})" in solver_detail,
           "the Rust Kohn-Sham solver read exactly this file of gammas",
           KS_RUST, ["gamma_fixture_numeric", "block_reduction_numeric"])
```

`read_bytes()` reads the file as raw bytes, `hashlib.sha256(...)` computes its fingerprint and `.hexdigest()` writes it as 64 hexadecimal digits (the digits 0 to 9 and the letters a to f). The Rust solver printed the first 16 digits of the fingerprint of the file it read into its check `gamma_fixture_numeric`; the check passes when the solver's text contains exactly ours, and when the solver's check `block_reduction_numeric` passed (it confirms that the solver's 2×2 blocks are the 16-component Hamiltonian written in another basis). Output: the 16 digits `c99277bab4793c42` and PASS the Rust Kohn-Sham solver read exactly this file of gammas. So the Kohn-Sham source of this chapter was computed with the author's eight real 16×16 matrices and no others.

In [5], the eight matrices as heat maps (figure 1).

```
LABELS = ["x_1", "x_2", "x_3", "x_4", "x_5", "x_6", "x_7", "x_0"]
fig, axes = plt.subplots(2, 4, figsize=(9.6, 5.4))
for a, ax in enumerate(axes.flat):
    image = ax.imshow(gamma[a], cmap="RdBu_r", vmin=-1.0, vmax=1.0)
    sign = "+1" if eta[a] > 0 else "-1"  # the square of this gamma matrix
    ax.set_title(f"$\\gamma^{{({LABELS[a]})}}$, square ${sign}$", fontsize=10)
```

A figure of two rows of four panels; `axes.flat` walks through the eight panels row by row, and `enumerate` numbers them $a = 0, \ldots, 7$ (the matrix of x_{a+1}). `imshow` draws the matrix with the colour scale `RdBu_r` (red, white, blue reversed: red for $+1$, white for 0, blue for -1), fixed between -1 and 1 by `vmin` and `vmax`. The title names the matrix and the sign of its square, $(\gamma^a)^2 = \eta^{aa}$ times the unit matrix.

```
    ax.set_xticks([0, 15], ["1", "16"])  # column numbers 1 and 16
    ax.set_yticks([0, 15], ["1", "16"])  # row numbers 1 and 16
    ax.tick_params(labelsize=7)  # small numbers, so that they do not collide
    ax.grid(False)  # no grid lines over the entries
fig.colorbar(image, ax=axes, shrink=0.75, label="matrix entry", ticks=[-1, 0, 1])
nonzero_count = int(sum(np.count_nonzero(matrix) for matrix in gamma))
```

Only the first and the last row and column are numbered (Python counts from 0, the book from 1); one colour bar serves all eight panels (`ax=axes`, shrunk to 75 per cent). `nonzero_count` counts the nonzero entries of all eight matrices: `np.count_nonzero` counts them in one matrix, and `sum` adds the eight counts.

```
save_figure(fig, "eight_gammas",
            "The author's eight real $16 \\times 16$ gamma matrices "
            "$\\gamma^{(x_0)}$ to $\\gamma^{(x_7)}$ as heat maps (rows 1 to 16 down, "
            "columns 1 to 16 across; red $+1$, blue $-1$, white $0$). Each row and "
            "each column holds exactly one nonzero entry, so the eight matrices "
            f"have {nonzero_count} nonzero entries in all; the squares are $+1$ "
            "for the space-like directions $x_0, x_1, x_2, x_3$ and $-1$ for the "
            "time $x_4$ and the deflating extra times $x_5, x_6, x_7$. These are "
            "the matrices with which the Kohn-Sham source of this chapter was "
            "computed.")
```

The caption is joined from its strings, as in Notebook 17a, In [6]; its one computed piece is `nonzero_count`, $8 \times 16 = 128$. Output: figure 17b.1 and its saved line.

What figure 17b.1 shows. Eight 16×16 tables, rows 1 to 16 downwards and columns 1 to 16 across, entries coloured red $(+1)$, blue (-1) or white (0). Every panel has exactly 16 coloured squares, one in each row and each column; the patterns and the signs differ from matrix to matrix (some lie along the diagonal from the lower left to the upper right, others in two blocks away from the diagonal). The squares are $+1$ for the space-like directions x_0, x_1, x_2, x_3 and -1 for the time x_4 and the deflating extra times x_5, x_6, x_7. The student should see that these are honest real matrices of whole numbers, the same that the Kohn-Sham source was computed with.

In [6], the hidden coordinate y, derived.

```
H = sp.symbols("H", positive=True)  # the constant H of the metric
X0 = sp.symbols("x0", positive=True)  # the author's hidden coordinate
z = 6 * H * X0  # the angle z = 6 H x0
y_of_x0 = sp.log(sp.sin(z)) / (6 * H)  # the hidden coordinate y
dy_dx0 = sp.simplify(sp.diff(y_of_x0, X0))  # chain rule
g_yy = sp.simplify(sp.cot(z) ** 2 / dy_dx0 ** 2)  # g00 times (dx0/dy)^2
say(f"dy/dx0 = {dy_dx0},  g_yy = {g_yy}")
```

Symbols for H and x_0, both positive; the angle z and $y = \ln(\sin z)/(6H)$ as sympy expressions. `sp.diff` differentiates with respect to x_0 (sympy applies the chain rule) and `sp.simplify` simplifies: the result is $\cot z$, printed as `1/tan(6*H*x0)`. The metric entry in the new coordinate is $g_{yy} = g_{00}\,(dx_0/dy)^2 = \cot^2 z / \cot^2 z = 1$ (rule: a length $\sqrt{g_{00}}\,dx_0$ is the same in both coordinates, and $dx_0 = dy/(dy/dx_0)$). Output: `dy/dx0 = 1/tan(6*H*x0),  g_yy = 1`.

```
s, c, a4_value = sp.symbols("s c a4", positive=True)  # s = sin z, c = cos z
y_of_s = sp.log(s) / (6 * H)  # y written with s = sin z
warp = sp.simplify(sp.exp(2 * H * y_of_s))  # e^{2Hy} in terms of s
say(f"e^(2Hy) = {warp}  (the warp factor sin^(1/3) z)")
```

To let sympy simplify powers safely, $\sin z$ and $\cos z$ are replaced by positive symbols s and c (both are positive on the patch), and a_4 by a positive symbol (only for this simplification; any value would do, since it cancels). Then $e^{2Hy} = e^{2H\ln(s)/(6H)} = e^{\ln(s)/3} = s^{1/3}$ (rule: $e^{\ln s} = s$ and $e^{k\ln s} = s^k$). Output: `e^(2Hy) = s**(1/3)`: the warp factor $\sin^{1/3} z$ is e^{2Hy}.

```
factors = ([sp.exp(2 * a4_value) * s ** sp.Rational(1, 3)] * 3 + [1]
           + [sp.exp(-2 * a4_value) * s ** sp.Rational(1, 3)] * 3)  # |g_ii|, i < 8
```

```
root_x0 = sp.simplify(sp.sqrt(sp.prod(factors) * (c / s) ** 2))  # g00 = cot^2 z
root_y = sp.simplify(sp.sqrt(sp.prod(factors) * 1))  # g_yy = 1
say(f"sqrt|det g| in the x0 chart = {root_x0};  in the y chart = {root_y}")
```

`factors` lists the absolute values of the seven diagonal entries other than g_{00} (`[x] * 3` repeats an entry three times; `sp.Rational(1, 3)` is the exact fraction 1/3). `sp.prod` multiplies them: $e^{6a_4}s \cdot 1 \cdot e^{-6a_4}s = s^2$. Times $g_{00} = \cot^2 z = (c/s)^2$ this is c^2, whose square root is $c = \cos z$; times $g_{yy} = 1$ it is s^2, whose square root is $s = \sin z = e^{6Hy}$. Output: `sqrt|det g| in the x0 chart = c; in the y chart = s`.

```
reproduces(sp.simplify(dy_dx0 - sp.cot(z)) == 0 and g_yy == 1
           and warp == s ** sp.Rational(1, 3) and root_x0 == c and root_y == s,
           "dy/dx0 = cot z, g_yy = 1, sin^(1/3) z = e^(2Hy), sqrt|g| = cos z or e^(6Hy)",
           KS_PY, ["geometry_hidden_coordinate", "geometry_sqrt_det",
                   "geometry_warped_form"])
```

The check collects the four results and reproduces three checks of the Kohn-Sham theory report. Output: the PASS line.

In [7], the covariant divergence of a general source in the coordinate x0.

```
def christoffel(metric, chart):
    """All Gamma^l_{mn} of a diagonal metric, as a nested list [l][m][n]."""
    inverse = [1 / metric[k, k] for k in range(8)]  # diagonal: g^kk = 1 / g_kk
    return [[[sp.simplify(inverse[l] * (sp.diff(metric[l, m], chart[n])
                                        + sp.diff(metric[l, n], chart[m])
                                        - sp.diff(metric[m, n], chart[l])) / 2)
              for n in range(8)] for m in range(8)] for l in range(8)]
```

`christoffel` computes all $8 \times 8 \times 8 = 512$ symbols $\Gamma^l{}_{mn}$ of a diagonal metric with the formula of Section 17.13, $\Gamma^l{}_{mn} = \frac{1}{2g_{ll}}(\partial_m g_{ln} + \partial_n g_{lm} - \partial_l g_{mn})$. `chart` is the list of the eight coordinates; `metric[l, m]` is an entry of the sympy matrix; the three nested list comprehensions build a list of lists of lists, so that `G[l][m][n]` is $\Gamma^l{}_{mn}$.

```
def divergence(T, metric, chart):
    """The 8 components nabla_mu T^mu_nu of a table T[mu, nu] = T^mu_nu."""
    G = christoffel(metric, chart)
    result = []
    for nu in range(8):
        total = 0
        for mu in range(8):
            total += sp.diff(T[mu, nu], chart[mu])  # d_mu T^mu_nu
            for lam in range(8):
                total += G[mu][mu][lam] * T[lam, nu]  # Gamma^mu_{mu lam} T^lam_nu
                total -= G[lam][mu][nu] * T[mu, lam]  # Gamma^lam_{mu nu} T^mu_lam
        result.append(sp.simplify(total))
    return result
```

`divergence` programs the definition of Section 17.13 term by term, without the shortcut of the lemma: for each ν it adds $\partial_\mu T^\mu{}_\nu$, adds $\Gamma^\mu{}_{\mu\lambda} T^\lambda{}_\nu$ and subtracts $\Gamma^\lambda{}_{\mu\nu} T^\mu{}_\lambda$ over all μ and λ (`+=` adds

to the running total, `-=` subtracts), simplifies, and appends the result. The table may be any 8×8 matrix, with mixed entries too.

```
coords = sp.symbols("x0:8", real=True)  # x0, ..., x7 (the x0 chart)
x4, x0 = coords[4], coords[0]
a4 = sp.Function("a4")(x4)  # the free function of the metric
zz = 6 * H * x0  # z = 6 H x0
wz = sp.sin(zz) ** sp.Rational(1, 3)  # the warp factor sin^(1/3) z
metric_x0 = sp.diag(*([sp.cot(zz) ** 2] + [sp.exp(2 * a4) * wz] * 3 + [-1]
                      + [-sp.exp(-2 * a4) * wz] * 3))  # x0, ..., x7 (b4 = 1)
```

`sp.symbols("x0:8")` makes the eight symbols `x0` to `x7` (the range 1:9 stops before 9); position 3 is x_4 and position 7 is x_0. `sp.Function("a4")(x4)` is an unknown function $a_4(x_4)$, which sympy differentiates as a_4'. `sp.diag(*list)` builds the diagonal matrix of the author's metric from the list of its eight entries (the star passes the entries one by one).

```
names = ("rho", "p3", "pt", "p0", "q40", "q04")
rho, p3, pt, p0, q40, q04 = (sp.Function(n)(x4, x0) for n in names)
T_x0 = sp.diag(p0, p3, p3, p3, -rho, pt, pt, pt)  # the diagonal part
T_x0[4, 0] = q40  # T^x4_x0
T_x0[0, 4] = q04  # T^x0_x4
div_x0 = divergence(T_x0, metric_x0, coords)
```

The six parts of the most general source are unknown functions of x_4 and x_0. The table is the diagonal matrix with the two mixed entries placed in row x_4, column x_0 and the reverse. `div_x0` is the list of the eight components of its divergence.

```
notation = {sp.Derivative(f, v): sp.Symbol(f"d{v.name[1]}{f.func.__name__}")
            for f in (rho, p3, pt, p0, q40, q04) for v in (x4, x0)}
notation[sp.Derivative(a4, x4)] = sp.Symbol("ad1")  # a4'

def in_record_notation(expression):
    """Write derivatives as d4rho, d0p0, ... and functions as plain symbols."""
    expression = expression.subs(notation)
    return expression.subs({f: sp.Symbol(f.func.__name__)
                            for f in (rho, p3, pt, p0, q40, q04)})
```

To print the result in the record's notation, each partial derivative is replaced by a short symbol: `v.name[1]` is the digit of the coordinate (4 or 8) and `f.func.__name__` the name of the function, so $\partial\rho/\partial x_4$ becomes `d4rho` and $\partial p_0/\partial x_0$ becomes `d0p0`; a_4' becomes `ad1`. `in_record_notation` makes these replacements and then writes each function as a plain symbol.

```
cc = sp.Symbol("cc")  # the record writes cot z as cc

def readable(expression):
    """A component as a sum of source symbols times simplified coefficients."""
    plain = sp.expand(in_record_notation(expression))
```

```
    sources = sorted(plain.free_symbols - {H, x0, sp.Symbol("ad1")}, key=str)
    total = sp.Integer(0)  # the sum, built term by term
    for symbol, factor in sp.collect(plain, sources, evaluate=False).items():
        factor = factor.subs(sp.sin(2 * zz), 2 * sp.sin(zz) * sp.cos(zz))
        factor = sp.simplify(factor.subs(sp.tan(zz), sp.sin(zz) / sp.cos(zz)))
        factor = sp.simplify(factor.subs(sp.sin(zz), sp.cos(zz) / cc))
        total += factor * symbol  # sin z = cos z / cot z
    return total.subs(sp.tan(zz), 1 / cc)
```

`readable` writes a component as a sum "coefficient times source quantity", with the coefficients in terms of `cc` $= \cot z$ as in the record. After multiplying out, `sources` is the sorted list of the source symbols that occur (all symbols except H, x_0 and `ad1`; `key=str` sorts by name). `sp.collect(..., evaluate=False)` returns a dictionary from each source symbol to its coefficient. Each coefficient is rewritten with $\sin 2z = 2\sin z\cos z$ and $\tan z = \sin z/\cos z$, simplified, and then written with $\sin z = \cos z/\cot z$, so that only $\cot z$ remains; the terms are added up, and a remaining $\tan z$ is written as $1/\cot z$.

```
for nu, component in enumerate(div_x0):
    say(f"nabla_mu T^mu_x{nu} = {readable(component)}")
```

The eight components are printed. Output: six zeros, and

`nabla_mu T^mu_x0 = 6*H*cc*p0 - 3*H*cc*p3 - 3*H*cc*pt + d0p0 + d4q40`,

`nabla_mu T^mu_x4 = -6*H*q04/cc - 3*ad1*p3 + 3*ad1*pt + d0q04 - d4rho`,

which are the two laws of Section 17.13 in the coordinate x_0 (since $1/\cot z = \tan z$).

In [8], comparison with the record.

```
equations = read_json(EQUATIONS)
RECORD_NAMES = {"ad1": sp.Derivative(a4, x4), "H": H, "cc": sp.cot(zz),
                "rho": rho, "p3": p3, "pt": pt, "p0": p0, "q40": q40, "q04": q04}
RECORD_NAMES.update({str(symbol): derivative
                     for derivative, symbol in notation.items()})
```

`RECORD_NAMES` translates the names of the record's text back into sympy objects: `ad1` into the derivative a_4', `cc` into $\cot z$, the source names into the functions, and (through `update` with the dictionary `notation` read backwards) `d4rho` into $\partial\rho/\partial x_4$ and so on.

```
def record_equation(text):
    """An equation left == right of the record as the expression left - right."""
    left, right = text.replace("^", "**").split("==")
    return (sp.sympify(left, locals=RECORD_NAMES)
            - sp.sympify(right, locals=RECORD_NAMES))
```

As `equation` in Notebook 17a: the record's text `left == right` becomes the expression left minus right.

```
same = []
for key, nu in (("conservation_x4", 4), ("conservation_x0", 0)):
    recorded = record_equation(equations["generalSource"][key]["input"])
    difference = sp.simplify((div_x0[nu] - recorded).rewrite(sp.cos))
    same.append(difference == 0)
    say(f"{key}: ours minus the record = {difference}")
zero_components = all(div_x0[nu] == 0 for nu in (1, 2, 3, 5, 6, 7))
reproduces(all(same) and zero_components,
           "our divergence equals the record: x4 and x0 laws, six zero components",
           PY_A4, ["conservation_components", "json_conservation"])
```

For the record's two laws (positions 3 and 7 are x_4 and x_0) the difference between our component and the record's is rewritten with cosines only (`.rewrite(sp.cos)`) and simplified; sympy finds 0 (one term needs the identity $\tan z + \cot z = 2/\sin 2z$, which the rewriting handles). Output: `conservation_x4:  ours minus the record = 0`, the same for `conservation_x0`, and the PASS line reproducing the sympy report's checks `conservation_components` and `json_conservation`. (PROVED.)

In [9], the conservation law in the coordinate y.

```
yc = sp.symbols("y", real=True)  # the hidden coordinate y
chart_y = [yc] + list(coords[1:])  # y (for x0), x1, ..., x7
wy = sp.exp(2 * H * yc)  # the warp factor e^{2Hy} = sin^(1/3) z
metric_y = sp.diag(*([1] + [sp.exp(2 * a4) * wy] * 3 + [-1]
                     + [-sp.exp(-2 * a4) * wy] * 3))
```

The coordinate y replaces x_0 (`coords[:7]` are the first seven coordinates); the metric is the warped form of Section 17.13, with $g_{yy} = 1$.

```
RHO, P3, PT, P0 = (sp.Function(n)(x4, yc) for n in ("rho", "p3", "pt", "p0"))
T_y = sp.diag(P0, P3, P3, P3, -RHO, PT, PT, PT)  # a diagonal source T(x4, y)
div_y = divergence(T_y, metric_y, chart_y)
law_x4 = -sp.diff(RHO, x4) - 3 * sp.diff(a4, x4) * (P3 - PT)
law_y = sp.diff(P0, yc) + 6 * H * P0 - 3 * H * (P3 + PT)
```

A diagonal source whose four parts are unknown functions of x_4 and y (capital names, to keep them apart from those of In [7]); its divergence with the same helper; and the two laws of Section 17.13 typed in by hand, for comparison.

```
derivatives = {sp.Derivative(RHO, x4): sp.Symbol("d4rho"),
               sp.Derivative(P0, yc): sp.Symbol("dyp0"),
               sp.Derivative(a4, x4): sp.Symbol("ad1")}  # short names
functions = {f: sp.Symbol(f.func.__name__) for f in (RHO, P3, PT, P0)}

def short(expression):
    """Write the derivatives as d4rho, dyp0, ad1 and the functions as symbols."""
    return expression.subs(derivatives).subs(functions)
```

Short names for printing, as in In [7]: `dyp0` is $\partial p_0/\partial y$.

```
say(f"nabla_mu T^mu_x4 = {short(div_y[4])}")
say(f"nabla_mu T^mu_y = {short(div_y[0])}")
others_zero = all(div_y[nu] == 0 for nu in (1, 2, 3, 5, 6, 7))
theory = read_json(KS_THEORY)["emt"]  # the energy-momentum part of the record
say("ks-theory.json, emt.conservationY: " + theory["conservationY"])
reproduces(sp.simplify(div_y[4] - law_x4) == 0 and sp.simplify(div_y[0] - law_y) == 0
           and others_zero
           and "6H p0 = 3H (p3 + p_t)" in theory["conservationY"],
           "in the y chart: the x4 law and dp0/dy + 6H p0 = 3H (p3 + p_t)",
           KS_PY, ["emt_y_conservation_selfconsistent", "emt_x4_component"])
```

The two surviving components are printed, the six others are confirmed to vanish, the record's statement of the y law is printed, and the check requires our components to equal the hand-typed laws and the record to state the same law. Output: `nabla_mu T^mu_x4 = -3*ad1*p3 + 3*ad1*pt - d4rho`, `nabla_mu T^mu_y = -3*H*p3 + 6*H*p0 - 3*H*pt + dyp0`, the record's line `p0' + 6H p0 = 3H (p3 + p_t) for every self-consistent state`, and the PASS line. (PROVED.)

In [10], the key identity.

```
p3_from_law = sp.solve(sp.Eq(law_y, 0), P3)[0]  # p3 from the y conservation law
V = P3 + PT - 2 * P0  # the violation of C2
V_conserved = sp.simplify(V.subs(P3, p3_from_law))
say(f"p3 from the conservation law: {short(p3_from_law)}")
say(f"V = p3 + p_t - 2 p0 for a conserved source: {short(V_conserved)}")
check(sp.simplify(V_conserved - sp.diff(P0, yc) / (3 * H)) == 0,
      "PROVED: for a conserved source V = p3 + p_t - 2 p0 = (dp0/dy) / (3H)")
```

`sp.Eq(law_y, 0)` is the equation "the y law equals 0", and `sp.solve(..., P3)` solves it for p_3; it returns a list of solutions, of which `[0]` takes the first (and only) one: $p_3 = 2p_0 - p_t + p_0'/(3H)$. Inserting it into V gives $p_0'/(3H)$, the derivation of Section 17.14. Output: `p3 from the conservation law: 2*p0 - pt + dyp0/(3*H)`, `V = p3 + p_t - 2 p0 for a conserved source:  dyp0/(3*H)` and the PASS line. (PROVED.)

In [11], the identity on the recorded states.

```
COLUMNS = ("rho", "p3", "p_t", "p0")  # the four diagonal components

def read_profile(path):
    """A profile table as a dictionary: column name -> numpy array (151 values)."""
    data = np.genfromtxt(path, delimiter=",", names=True)
    return {name: data[name] for name in data.dtype.names}

files = sorted(repository_file(f"{GROUND}/profiles").glob("*.csv"),
               key=lambda path: path.name)
profiles = {path.stem: read_profile(path) for path in files}
with repository_file(f"{GROUND}/emt-integrals.csv").open(
        encoding="utf-8", newline="") as handle:
    integrals = {row["id"]: row for row in csv.DictReader(handle)}
physics = read_json("Revision/kohn_sham/results/parameters.json")["physics"]
```

```
H_value, L_cut, VOL7 = physics["H"], physics["L_tipCutoff"], physics["Vol7"]
scale = {sid: float(max(np.max(np.abs(prof[c])) for c in COLUMNS))
         for sid, prof in profiles.items()}  # max|T| of every state
nonzero = [sid for sid in profiles if scale[sid] > 0.0]
y = profiles["N136_lam0_a10"]["y"]  # the common grid of y
h = float(y[1] - y[0])  # the grid step
```

These lines read the 75 profiles, the table of integrals and the parameters, and compute max|T| and the list of nonzero states, exactly as Notebook 17a did (Section 17.11, In [5]). The only new line is the grid step `h`, the distance between two neighbouring grid points, 0.02.

```
def slope(values, s=1):
    """dv/dy at the points i = 2s, ..., 150 - 2s (fourth order, step s h)."""
    v = values
    return (-v[4 * s:] + 8 * v[3 * s:-s] - 8 * v[s:-3 * s] + v[:-4 * s]) / (12 * h * s)
```

`slope` estimates the derivative of a tabulated function with the **fourth-order central difference** of step $\delta = sh$:

$$f'(y) \approx \frac{-f(y+2\delta) + 8f(y+\delta) - 8f(y-\delta) + f(y-2\delta)}{12\,\delta}.$$

Why fourth order? Expand each value in a Taylor series around y: $f(y \pm \delta) = f \pm \delta f' + \frac{\delta^2}{2} f'' \pm \frac{\delta^3}{6} f''' + \frac{\delta^4}{24} f'''' \pm \frac{\delta^5}{120} f^{(5)} + \ldots$, and the same with 2δ. Line by line:

$$8\big[f(y+\delta) - f(y-\delta)\big] = 16\delta f' + \tfrac{16}{6}\delta^3 f''' + \tfrac{16}{120}\delta^5 f^{(5)} + \ldots$$

(rule: in the difference the even powers cancel and the odd powers double)

$$-\big[f(y+2\delta) - f(y-2\delta)\big] = -4\delta f' - \tfrac{16}{6}\delta^3 f''' - \tfrac{64}{120}\delta^5 f^{(5)} - \ldots$$

(rule: the same with 2δ: $2 \cdot 2\delta = 4\delta$, $2(2\delta)^3/6 = 16\delta^3/6$, $2(2\delta)^5/120 = 64\delta^5/120$)

$$\text{sum} = 12\delta f' - \tfrac{48}{120}\delta^5 f^{(5)} + \ldots, \qquad \frac{\text{sum}}{12\delta} = f' - \frac{\delta^4}{30} f^{(5)} + \ldots$$

(rule: add; the δ^3 terms cancel; divide by 12δ, and $\frac{48}{120 \cdot 12} = \frac{1}{30}$). The error is proportional to δ^4: halving the step divides it by 16. In the code, for the array `v` of 151 values, `v[4*s:]` are the values $f(y_i + 2\delta)$ for the points $i = 2s, \ldots, 150 - 2s$, `v[3*s:-s]` the values $f(y_i + \delta)$, `v[s:-3*s]` the values $f(y_i - \delta)$ and `v[:-4*s]` the values $f(y_i - 2\delta)$; all four arrays have $151 - 4s$ entries, and the formula acts on them entry by entry. The first and last $2s$ points have no neighbours on one side and get no slope.

```
def violation(prof):
    """V(y) = p3 + p_t - 2 p0 of a profile."""
    return prof["p3"] + prof["p_t"] - 2.0 * prof["p0"]
```

```
residual = {sid: float(np.max(np.abs(slope(profiles[sid]["p0"]) / (3 * H_value)
                                     - violation(profiles[sid])[2:-2])))
            / scale[sid] for sid in nonzero}
worst = max(residual, key=residual.get)  # the state with the largest difference
```

`violation` returns $V(y)$ of a profile. For each nonzero state, `residual` is the largest difference between $p_0'/(3H)$ (from `slope` with $s = 1$) and V at the inner points (`[2:-2]` drops two points at each end, to match), divided by max|T|. `worst` is the state with the largest value.

```
report("states with a nonzero tensor", len(nonzero))
report("grid step h", f"{h:.2f}")
report("largest |(dp0/dy)/(3H) - V| / max|T| over 70 states", f"{residual[worst]:.2e}",
       f"({worst})")
check(len(nonzero) == 70 and residual[worst] < 1e-3,
      "V = (dp0/dy)/(3H) on every state to 1e-3 of max|T| (fourth-order differences)")
```

The third `report` passes the state's name in brackets as its third argument, the place of the unit, so that it is printed after the number. `:.2e` writes a number with two decimals in the computer's power-of-ten form, `1.05e-04` for 1.05×10^{-4}. Output: 70 states, $h = 0.02$, the largest difference 1.05×10^{-4} of max|T| (state `N8_lamm1_a00`), and the PASS line. (COMPUTED; the bound 10^{-3} was fixed before the run. The solver, on its own grid of 900 steps of $3/900 = 1/300$ (six times finer than the stored grid of 150 steps of 0.02), checks the same law with fourth-order differences to a relative residual of at most 1.951×10^{-8}: `Revision/kohn_sham/reports/ks-rust-solver.json`, check `emt_y_conservation_pointwise`; the number of steps is the record `Revision/kohn_sham/results/parameters.json`, key `numerics.rk4Steps`.)

In [12], the identity drawn (figure 2).

```
SLICES = {"a00": 0.0, "a05": 0.5, "a10": 1.0, "a15": 1.5, "a20": 2.0}  # a4,0
SHADES = ["#86b6ef", "#5598e7", "#2a78d6", "#1c5cab", "#104281"]  # light to dark
history136 = [f"N136_lam0_{tag}" for tag in SLICES]
fig, (left, right) = plt.subplots(1, 2, figsize=(9.6, 4.0))
for shade, sid, a40 in zip(SHADES, history136, SLICES.values()):
    left.plot(y, profiles[sid]["p0"] / scale[sid], color=shade, lw=1.8,
              label=f"$a_{{4,0}} = {a40:g}$")
left.set_yscale("symlog", linthresh=1e-6)
left.set_xlabel("hidden coordinate $y$ (tip $-3$, brane $0$)")
left.set_ylabel("$p_0(y)$ / max|T|")
left.set_title("$N = 136$, $\\lambda = 0$: $p_0$ is far from flat")
left.legend(fontsize=7, loc="upper right")
```

The slices, shades and the history $N = 136$, $\lambda = 0$ as in Notebook 17a. The left panel draws $p_0 / \max|T|$ of the five states on a symmetric logarithmic axis, linear between -10^{-6} and 10^{-6}.

```
example = profiles["N136_lam0_a10"]
inner = y[2:-2]  # the points where the slope is known
right.plot(y, violation(example) / scale["N136_lam0_a10"], color="#2a78d6",
```

```
           lw=2.0, label="$V = p_3 + p_t - 2p_0$")
right.plot(inner[::5], (slope(example["p0"]) / (3 * H_value))[::5]
           / scale["N136_lam0_a10"], "o", color="#eb6834", ms=3.5,
           label="$p_0'(y)/(3H)$")
right.axhline(0.0, color="#e34948", ls="--", lw=1.0, label="C2: $V = 0$")
right.set_yscale("symlog", linthresh=1e-6)
right.set_xlabel("hidden coordinate $y$")
right.set_ylabel("divided by max|T|")
right.set_title("$a_{4,0} = 1$: the two sides of the identity")
right.legend(fontsize=7, loc="upper right")
fig.tight_layout()
```

The right panel draws, for the slice $a_{4,0} = 1$, the violation V as a blue line over all points and $p_0'/(3H)$ as orange dots at every fifth inner point (`[::5]` takes every fifth entry), both divided by max|T|, with the red dashed line $V = 0$ and the same kind of axis.

```
p0_range = [float(np.max(np.abs(profiles[s]["p0"])) / np.min(np.abs(profiles[s]["p0"])))
            for s in history136]  # how far p0 is from flat, per slice
```

`p0_range` holds, per slice, the largest $|p_0|$ divided by the smallest.

```
save_figure(fig, "slope_identity",
            "Left: the hidden-direction pressure $p_0(y)$ of the Kohn-Sham states "
            "$N = 136$, $\\lambda = 0$ at the five slices $a_{4,0} = 0$ to $2$, "
            "divided by the largest component of each state (horizontal axis: the "
            "hidden coordinate $y$; vertical axis symmetric logarithmic, linear "
            "between $-10^{-6}$ and $10^{-6}$); the largest $|p_0|$ is "
            f"{min(p0_range):.0f} to ${tex_number(max(p0_range))}$ times the "
            "smallest, while "
            "condition C2 of a conserved source demands a flat $p_0$. Right: for "
            "$a_{4,0} = 1$ the violation $V = p_3 + p_t - 2p_0$ (blue line) and the "
            "slope $p_0'(y)/(3H)$ from fourth-order differences (orange dots) lie "
            "on top of each other, as the conservation law demands; the dashed "
            "line is the value $0$ that C2 needs.")
```

The caption, joined from its strings, inserts the range of `p0_range`: the smallest with no decimals, 2933, and the largest in powers of ten, 2.3×10^6. The prime in the text $p_0'(y)$ is an ordinary character of a string written in double quotation marks. Output: figure 17b.2 and its saved line.

What figure 17b.2 shows. Left: horizontal axis y (units of $1/H$), vertical axis $p_0/\max|T|$ (a pure number, symmetric logarithmic). At the tip p_0 is negative and as large as max|T| (the -10^0 at the lower left); it rises steeply, crosses zero between $y \approx -2.6$ and $y \approx -2.35$, reaches a maximum and falls toward the brane by several powers of ten. For C2, by Section 17.14, every curve would have to be horizontal. Right: the blue line V and the orange dots $p_0'/(3H)$ lie on top of each other along the whole patch, positive on the tip side of the maximum of p_0 and negative on the brane side: the student sees the identity $V = p_0'/(3H)$ at work, and why V changes sign once.

In [13], the differences have order 4 (figure 3).

```
STEPS = np.array([1, 2, 3, 5, 6])  # the step is s h
POINTS = [30, 60, 90, 120]  # grid indices of y = -2.4, -1.8, -1.2, -0.6
```

```

         "N688_lamm2_a00"]
```

Five step multipliers s; four grid points (index i is $y = -3 + 0.02\,i$: index 30 is $y = -2.4$, and so on); five states of all three particle numbers.

```
def difference_at_points(sid, s):
    """max over POINTS of |(dp0/dy)/(3H) - V| / max|T| with the step s h."""
    prof = profiles[sid]
    derivative = slope(prof["p0"], s) / (3 * H_value)  # index i - 2s is point i
    return max(abs(float(derivative[i - 2 * s] - violation(prof)[i]))
               for i in POINTS) / scale[sid]
```

For one state and one step: the slope array starts at the grid point $2s$, so its entry `i - 2*s` belongs to the grid point i; the function returns the largest difference $|p_0'/(3H) - V|$ at the four points, divided by max|T|.

```
errors = {sid: np.array([difference_at_points(sid, s) for s in STEPS])
          for sid in STUDY}
orders = {sid: float(np.polyfit(np.log(STEPS * h), np.log(errors[sid]), 1)[0])
          for sid in STUDY}  # the slope of the straight-line fit
for sid in STUDY:
    say(f"{sid}: differences " + ", ".join(f"{e:.1e}" for e in errors[sid])
        + f";  fitted order {orders[sid]:.2f}")
check(all(3.8 < order < 4.2 for order in orders.values()),
      "the differences fall like (step)^4: they are errors of the differences")
```

`errors` holds the five differences of each state. If the difference is an error of order 4, it is $C\delta^4$ with a constant C, so $\ln(\text{difference}) = \ln C + 4\ln\delta$: a straight line of slope 4 in the logarithms. `np.polyfit(x, y, 1)` fits a straight line $y \approx c_1 x + c_0$ by least squares and returns $[c_1, c_0]$; `[0]` takes the slope. Output: one line per state, for example `N136_lam0_a10:  differences 4.6e-07, 7.5e-06, 3.8e-05, 3.0e-04, 6.5e-04; fitted order 4.04`; the fitted orders are 4.08, 4.04, 4.02, 4.04 and 4.04; and the PASS line. (COMPUTED.) Had the conservation law failed, the differences would stop falling at the size of the failure; instead they fall like δ^4 down to 5×10^{-7} of max|T| at the smallest step.

```
fig, ax = plt.subplots(figsize=(6.4, 4.4))
for sid in STUDY:
    ax.loglog(STEPS * h, errors[sid], "o-", lw=1.4, ms=4,
              label=f"{sid} (order {orders[sid]:.2f})")
reference = errors["N136_lam0_a10"][0] * (STEPS / STEPS[0]) ** 4.0
ax.loglog(STEPS * h, reference, "k--", lw=1.0, label="slope 4 (reference)")
ax.set_xlabel("step of the difference $s h$ (units of $1/H$)")
ax.set_ylabel("max $|p_0'/(3H) - V|$ / max|T|")
ax.legend(fontsize=7)
```

`ax.loglog` draws with both axes logarithmic; `"o-"` means circles joined by lines, and each state's legend entry carries its fitted order. The black dashed reference line (the format string is the letter

k, for black, and two hyphens, for dashes) starts at the first point of the state `N136_lam0_a10` and grows like the fourth power of the step: `STEPS / STEPS[0]` is the step relative to the smallest one, and `** 4.0` raises it to the fourth power.

```
save_figure(fig, "difference_order",
            "The difference between $p_0'(y)/(3H)$, computed with fourth-order "
            "differences of step $sh$ ($h = 0.02$, $s = 1, 2, 3, 5, 6$), and the "
            "violation $V = p_3 + p_t - 2p_0$, at the four points $y = -2.4$, "
            "$-1.8$, $-1.2$, $-0.6$, divided by the largest component of the state, "
            "for five recorded Kohn-Sham states (logarithmic axes; the step in units "
            "of $1/H$). The fitted slopes lie between "
            f"{min(orders.values()):.2f} and {max(orders.values()):.2f}, the order "
            "4 of the differences: the small differences are errors of the finite "
            "differences, and the conservation law itself holds.")
```

The caption, joined from its strings, inserts the smallest and the largest fitted order with two decimals, 4.02 and 4.08. Output: figure 17b.3 and its saved line.

What figure 17b.3 shows. Horizontal axis: the step sh from 0.02 to 0.12 (units of $1/H$); vertical axis: the largest difference divided by max|T| (pure number); both logarithmic. Five straight lines, parallel to the dashed reference of slope 4: the differences are pure errors of the finite differences, and the conservation law itself holds for the recorded states.

In [14], the integrated law.

```
def number(sid, column):
    """A number of the record's table of integrals."""
    return float(integrals[sid][column])

tip_weight = float(np.exp(-6.0 * H_value * L_cut))  # e^{-6HL}, about 1.5e-8
integrated = {}
for sid in nonzero:
    left_side = 2 * VOL7 * (number(sid, "p0_brane") - tip_weight * number(sid, "p0_tip"))
    right_side = 3 * H_value * (number(sid, "int_p3") + number(sid, "int_p_t"))
    integrated[sid] = abs(left_side - right_side) / abs(right_side)
worst_integrated = max(integrated, key=integrated.get)
report("largest relative difference of the integrated law",
       f"{integrated[worst_integrated]:.3e} ({worst_integrated})")
```

`number` reads a number of the table. `tip_weight` is $e^{-6HL} = e^{-18}$. For each nonzero state the two sides of the integrated law of Section 17.15 are computed from the table's columns `p0_brane`, `p0_tip`, `int_p3` and `int_p_t`, and their relative difference is stored. Output: the largest relative difference is 1.421×10^{-11} (state `N8_lamm2_a00`).

```
column = {sid: number(sid, "ycons_integrated_rel") for sid in nonzero}
column_worst = max(column, key=column.get)  # the solver's own largest value
report("largest value of the column ycons_integrated_rel",
       f"{column[column_worst]:.3e} ({column_worst})")
solver = record_entry(KS_RUST, "emt_y_conservation_integrated")["detail"]
say("the solver record: " + solver)
```

The table also has a column `ycons_integrated_rel`: the solver's own relative difference of the same two sides, computed from its unrounded internal numbers and divided by the largest of the terms involved (the integral, the boundary term, the tip term and the size of the cancelling terms), not by the right side alone as our number is; so the two are close cousins, not the same quantity by definition. Its largest value is 1.422×10^{-11}, also at `N8_lamm2_a00`, against our 1.421×10^{-11}. The text of the solver's check `emt_y_conservation_integrated` is printed: 75 cases, worst value 1.422×10^{-11} (`N8_lamp2_a00`), tolerance 10^{-7}, no failures.

```
named = solver.split("worst value ")[1].split("(")[1].split(")")[0]  # its state
tie = abs(column[named] - column[column_worst]) < 1e-15  # mirror states tie
report("the state named by the record and its column value",
       f"{named}, {column[named]:.3e}")
reproduces(integrated[worst_integrated] < 1e-10 and tie
           and f"worst value {column[column_worst]:.3e}" in solver,
           "the integrated conservation law holds for all 70 states",
           KS_RUST, ["emt_y_conservation_integrated"])
```

The state named by the record is cut out of its text: after `worst value` , after the next `(`, before the next `)`. The record names `N8_lamp2_a00`, our maximum is `N8_lamm2_a00`: the two states with $N = 8$ and $\lambda = \pm\lambda_2$ have tensors of opposite sign and equal size (the record's table: for example $\int \rho = \mp 0.00286265$), so their relative differences are equal, and `tie` confirms it to 10^{-15}. The check passes when our largest difference is below 10^{-10}, the tie holds and the record's worst value equals the column's. Output: the state and its value, and the PASS line. (COMPUTED. The pair $\pm\lambda$ of these zero-mode states is a property of these particular recorded states; it is not one of the pairing theorems of Chapters 18 to 20.)

In [15], why the averaged ratio is not 1.

```
mean_p0 = {sid: number(sid, "int_p0") / (2 * VOL7 * (1 - tip_weight) / (6 * H_value))
           for sid in nonzero}  # the weighted mean of p0
ratio = {sid: (number(sid, "int_p3") + number(sid, "int_p_t"))
         / (2 * number(sid, "int_p0")) for sid in nonzero}  # as in Notebook 17a
boundary = {sid: (number(sid, "p0_brane") - tip_weight * number(sid, "p0_tip"))
            / (1 - tip_weight) for sid in nonzero}  # the boundary value b0
from_brane = {sid: boundary[sid] / mean_p0[sid] for sid in nonzero}  # R = b0/mean
brane_only = {sid: number(sid, "p0_brane") / mean_p0[sid] for sid in nonzero}
tip_share = {sid: 1.0 - brane_only[sid] / from_brane[sid] for sid in nonzero}
```

Six dictionaries: the weighted mean $\bar{p}_0$ of Section 17.7; the ratio R as Notebook 17a computed it; the boundary value $b_0 = [p_0(0) - e^{-6HL} p_0(-L)]/(1 - e^{-6HL})$ of Section 17.15; R computed the other way, $b_0/\bar{p}_0$; the ratio that the brane value alone would give, $p_0(0)/\bar{p}_0$; and the share of R that the tip term supplies, $1 - p_0(0)/b_0$ (the quotient of the last two ratios, subtracted from 1).

```
step = float(y[1] - y[0])  # the grid step of y, 0.02

def simpson_rule(values):
    """Simpson's rule with the step of y (for an odd number of points)."""
    return step / 3 * (values[0] + values[-1] + 4 * values[1:-1:2].sum()
                       + 2 * values[2:-1:2].sum())
```

`step` is the distance between neighbouring points of the grid `y`, 0.02 (`float` turns the numpy number into an ordinary Python number). `simpson_rule` integrates a list of values given at the points of such a grid with **Simpson's rule**. On one pair of steps of width h the rule is $\int_a^{a+2h} f\,dy \approx \frac{h}{3}[f(a) + 4f(a+h) + f(a+2h)]$: the exact integral of the parabola through the three points (its error falls like h^4). For a grid with an even number of steps, that is an odd number of points $f_0, f_1, \ldots, f_{2n}$, the pairs are added: every inner point with an odd index is the middle of a pair and gets the weight 4, and every inner point with an even index is the end of one pair and the start of the next and gets the weight $1 + 1 = 2$:

$$\int f\,dy \approx \frac{h}{3}\big[f_0 + 4f_1 + 2f_2 + 4f_3 + \cdots + 2f_{2n-2} + 4f_{2n-1} + f_{2n}\big].$$

In the code, `values[0]` and `values[-1]` are the first and the last value (the index -1 counts from the end); `values[1:-1:2]` takes every second value from index 1 up to, but not including, the last one (the odd indices); `values[2:-1:2]` does the same from index 2 (the even inner indices); `.sum()` adds the values taken.

```
last_unit = y >= -1.0 - 1e-9  # the last unit before the brane: 51 points
near_share, table_gap = {}, {}
for sid in nonzero:
    weighted = np.exp(6 * H_value * y) * profiles[sid]["p0"]  # e^{6Hy} p0
    whole = simpson_rule(weighted)  # the integral over the whole patch
    near_share[sid] = simpson_rule(weighted[last_unit]) / whole
    table_gap[sid] = abs(2 * VOL7 * whole / number(sid, "int_p0") - 1.0)
```

`y >= -1.0 - 1e-9` compares every point of the grid with -1 and gives an array of `True` and `False` values, `True` for the 51 points $y = -1, -0.98, \ldots, 0$ (the tiny 10^{-9} makes sure that the point $y = -1$ counts even if the file stores it with a rounding error in the last digit). These 51 points have 50 steps, an even number, as Simpson's rule needs; the whole grid has 151 points and 150 steps. Two empty dictionaries are made, and the loop fills them for every nonzero state. `weighted` holds the 151 values of $e^{6Hy}p_0$; `whole` is its integral from $y = -3$ to 0. `weighted[last_unit]` keeps only the values at the points where `last_unit` is `True`, so `near_share` is the integral over $-1 \le y \le 0$ divided by the integral over the whole patch. Because the weighted mean $\bar{p}_0$ is this integral divided by a fixed number (Section 17.7), `near_share` is also the share of $\bar{p}_0$ that comes from the last unit before the brane. `table_gap` is a control: the table's `int_p0` is $2\,\mathrm{Vol}_7 \int e^{6Hy}p_0\,dy$ (Section 17.7), so `2 * VOL7 * whole` should equal it, and the relative difference is stored.

```
agreement = max(abs(from_brane[sid] / ratio[sid] - 1.0) for sid in nonzero)
closest = min(ratio, key=lambda sid: abs(ratio[sid] - 1.0))
report("largest relative difference of the two forms of R", f"{agreement:.1e}")
report("R closest to 1", f"{ratio[closest]:.6g} ({closest})")
report("largest relative difference, Simpson's integral of p0 and int_p0",
       f"{max(table_gap.values()):.1e}")
for n in (8, 136, 688):
    shares = [tip_share[sid] for sid in nonzero if sid.startswith(f"N{n}_")]
    report(f"share of R from the tip term, N = {n}",
           f"{min(shares):.2g} to {max(shares):.2g}")
    nears = [near_share[sid] for sid in nonzero if sid.startswith(f"N{n}_")]
    report(f"share of the mean of p0 from -1 <= y <= 0, N = {n}",
```

```
           f"{min(nears):.3f} to {max(nears):.3f}")
detail = record_entry(SOURCE_REPORT, "ks_integrals_violate_algebraic_condition")[
    "detail"]
reproduces(agreement < 1e-9
           and f"(closest to 1: {ratio[closest]:.6g} at {closest})" in detail,
           "R = b0 / mean of p0 (b0: brane value with the tip term), 70 states",
           SOURCE_REPORT, ["ks_integrals_violate_algebraic_condition"])
```

`agreement` is the largest relative difference of the two forms of R over all nonzero states. The third `report` prints the largest value of `table_gap`. The loop collects, for each particle number, the tip shares of its states (`startswith` tests the beginning of the name) and prints the smallest and the largest with two significant digits (`.2g`); then it does the same for the shares of the mean from the last unit, with three decimals (`.3f`). Output: 1.4×10^{-11}; the ratio closest to 1 is again 0.414328 (`N688_lamm2_a00`), the record's number; 4.7×10^{-9}, so the notebook's integral of the profile and the solver's table describe the same number; then, for each particle number, two lines: the tip shares, 0.31 to 0.33 for $N = 8$, 4.1×10^{-5} to 0.039 for $N = 136$ and 5.3×10^{-6} to 0.025 for $N = 688$, and the shares of the mean from $-1 \le y \le 0$, 0.439 to 0.441 for $N = 8$, 0.812 to 0.932 for $N = 136$ and 0.816 to 0.969 for $N = 688$; and the PASS line. (COMPUTED. So for the states with 3-momentum most of the mean of p_0 comes from the last unit before the brane and the tip term matters little; for the brane zero modes $N = 8$ less than half of the mean comes from there, and the tip term supplies about a third of R, Section 17.15.)

In [16], the boundary value against the mean (figure 4).

```
N_COLOURS = {8: "#1baf7a", 136: "#2a78d6", 688: "#eb6834"}
fig, ax = plt.subplots(figsize=(6.4, 5.0))
for n, colour in N_COLOURS.items():
    for positive in (True, False):
        ids = [sid for sid in nonzero if sid.startswith(f"N{n}_")
               and (mean_p0[sid] > 0) == positive]  # one sign at a time
        if not ids:
            continue
        ax.loglog([abs(mean_p0[sid]) for sid in ids],
                  [abs(boundary[sid]) for sid in ids], "o",
                  ms=5 if positive else 10,  # rings around the mirror states
                  color=colour, mfc=colour if positive else "none",
                  label=f"$N = {n}$" + ("" if positive else ", mean $< 0$"))
```

For each particle number and each sign of $\bar{p}_0$, the states of that kind are collected (`(mean > 0) == positive` selects one sign); an empty group is skipped. The points are drawn on logarithmic axes, which need positive numbers, so absolute values are used: horizontal $|\bar{p}_0|$, vertical the boundary value $|b_0|$ of In [15]. Their ratio is exactly R. States with a positive mean get small filled circles; states with a negative mean get larger rings (`mfc`, the marker face colour, is `"none"`, so only the outline is drawn).

```
line = np.array([1e-7, 1.0])  # the range of the diagonal
ax.loglog(line, line, "--", color="#e34948", lw=1.2,
          label="averaged C2: boundary value = mean")
ax.set_xlabel("weighted mean $|\\bar p_0|$ (units of $m^8$)")
ax.set_ylabel("boundary value $|b_0|$ (units of $m^8$)")
```

```
ax.legend(fontsize=8, loc="upper left")
negative = sorted(sid for sid in nonzero if mean_p0[sid] < 0)  # mean of p0 < 0
say("states with a negative mean of p0: " + ", ".join(negative))
expected = sorted(sid for sid in nonzero if sid.startswith("N8_lamp"))
```

The red dashed diagonal is where the boundary value equals the mean, the averaged C2 ($R = 1$). The cell prints the states with a negative mean, and `expected` lists the ten $N = 8$ states with $\lambda > 0$ (their names start with `N8_lamp`).

```
plotted = {sid: boundary[sid] / mean_p0[sid] for sid in nonzero}  # = R
save_figure(fig, "brane_and_mean",
            "The boundary value $b_0 = (p_0(0) - e^{-6HL}p_0(-L))/(1 - e^{-6HL})$ "
            "of the hidden-direction pressure against its weighted mean, for the "
            ...)
check(negative == expected and all(0.0 < plotted[sid] < 1.0 for sid in nonzero),
      "every point lies below the diagonal; mean of p0 < 0 only for N = 8, "
      "lambda > 0")
```

`plotted` holds the ratio of the vertical to the horizontal value of every point, $b_0/\bar{p}_0$, which is R. The caption is quoted shortened (it is printed in full under the figure); joined from its strings, it inserts the range of the plotted ratios with three decimals, 0.107 to 0.414, and the range that the brane value alone would give, 0.074 to 0.414 (`min` and `max` of the dictionaries `plotted` and `brane_only`). The check confirms that the states with a negative mean are exactly the expected ten, and that every plotted ratio lies strictly between 0 and 1 (Python allows the chained comparison `0.0 < r < 1.0`). Output: the list `N8_lamp1_a00` to `N8_lamp2_a20`, figure 17b.4 with its saved line, and then the PASS line (the check comes after the figure).

What figure 17b.4 shows. Both axes logarithmic, in units of m^8. The averaged C2 would put every point on the dashed diagonal. All 70 points lie below it: the boundary value of p_0 is between about a tenth and four tenths of its mean, the ratios $R = 0.107$ to 0.414 of Notebook 17a. For the $N = 136$ and $N = 688$ states the boundary value is practically the brane value; for the $N = 8$ states the brane value alone would be only 0.074 of the mean, and the tip term raises the ratio to about 0.11 (near the tip p_0 has the sign opposite to its mean, so $-e^{-6HL}p_0(-L)$ has the sign of the mean). The blue ($N = 136$) and orange ($N = 688$) points form two short chains, one point per slice (the couplings overlap); the 20 nonzero $N = 8$ states, equal at every slice, fall on only two places, where the filled points of $-\lambda_1$ and $-\lambda_2$ sit inside the rings of $+\lambda_1$ and $+\lambda_2$ (same size, opposite sign: for $+\lambda$ the mean and the brane value of p_0 are negative, while p_0 at the tip is positive).

In [17], the constraint propagates.

```
ad1, ad2 = sp.symbols("ad1 ad2", real=True)  # a4' and a4''
alpha = sp.symbols("alpha1:4", real=True)  # the Lovelock couplings
kappa, p3s, pts = sp.symbols("kappa p3 pt", real=True)  # kappa and the pressures
LOCALS = {"ad1": ad1, "ad2": ad2, "H": H, "alpha1": alpha[0], "alpha2": alpha[1],
          "alpha3": alpha[2]}
```

```
def parse(text):
    """A formula of the record (Wolfram Language text) as a sympy expression."""
    return sp.sympify(text.replace("^", "**"), locals=LOCALS)
```

New symbols: a_4' and a_4'', the three couplings (`"alpha1:4"` makes `alpha1`, `alpha2`, `alpha3`), κ and two pressures (named `p3s` and `pts` in the code, to keep them apart from the functions of In [7]). `parse` reads a formula of the record, as in Notebook 17a.

```
E44 = sum(alpha[k - 1] * parse(equations["lovelockTensors"][f"E{k}"]["x4x4"]["input"])
          for k in (1, 2, 3))  # sum_k alpha_k E_(k)^x4_x4
F = parse(equations["generalSource"]["evolution_F"]["input"])
rho_dot = -3 * ad1 * (p3s - pts)  # the x4 conservation law
constraint_dot = sp.diff(E44, ad1) * ad2 + kappa * rho_dot  # chain rule
evolution = ad2 * F - kappa * (p3s - pts)
```

`E44` is $e_{44} = \sum_k \alpha_k E_{(k)}{}^{x_4}{}_{x_4}$ from the record, `F` the record's F, `rho_dot` the energy-change law, `constraint_dot` the derivative $d\mathcal{C}/dx_4 = (de_{44}/da')\, a_4'' + \kappa\rho'$ of Section 17.16, and `evolution` the expression $\mathcal{E}$.

```
say(f"d/d(a4') of the x4 component: {sp.factor(sp.diff(E44, ad1))}")
say(f"3 a4' F: {sp.factor(3 * ad1 * F)}")
reproduces(sp.expand(constraint_dot - 3 * ad1 * evolution) == 0,
           "PROVED: dC/dx4 = 3 (da4/dx4) times the evolution equation, any alpha_k",
           WL_A4, ["constraint_propagation_bianchi"])
linear = sp.expand(constraint_dot.subs({ad2: 0, ad1: sp.Symbol("A") * H}))
say(f"along the linear member a4 = A H x4: dC/dx4 = {sp.factor(linear)}")
```

`sp.factor` writes an expression as a product of factors. The two printed lines show de_{44}/da' and $3a'F$; they are the same, $6a'(\alpha_1 - 24\alpha_2 a'^2 - 40\alpha_2 H^2 + 360\alpha_3 a'^4 + 432\alpha_3 a'^2 H^2 + 360\alpha_3 H^4)$, the fact derived by hand in Section 17.16. The check confirms $d\mathcal{C}/dx_4 - 3a_4'\mathcal{E} = 0$ for all couplings (PROVED; Wolfram report, check `constraint_propagation_bianchi`). Then $a_4'' = 0$ and $a_4' = AH$ are inserted. Output: the two factored lines, the PASS line and `along the linear member a4 = A H x4:  dC/dx4 = -3*A*H*kappa*(p3 - pt)`.

In [18], the energy exchange along the history.

```
history = read_json("Revision/kohn_sham/results/adiabatic/history.json")
no_crossing = all(not series["fermiLevelCrossings"] for series in history["series"])
TAGS = ["lamm2", "lamm1", "lam0", "lamp1", "lamp2"]  # the five couplings
simpson_error, energies, drives = {}, {}, {}
```

The solver's record of the history lists, for each of the 15 series, the places where a level crosses the Fermi level between slices; `not series["fermiLevelCrossings"]` is true when that list is empty. Comparing the energies of different slices is fair only if each state is followed continuously, so `no_crossing` must be true. `TAGS` are the coupling parts of the names; three empty dictionaries will collect the results.

```
for n in (8, 136, 688):
    for tag in TAGS:
        ids = [f"N{n}_{tag}_{s}" for s in SLICES]
        E = np.array([number(sid, "int_rho") for sid in ids])  # E at the slices
        drive = np.array([-3 * (number(sid, "int_p3") - number(sid, "int_p_t"))
```

```
                    for sid in ids])  # dE/da4 at the slices
        simpson = 0.5 / 3 * (drive[0] + 4 * drive[1] + 2 * drive[2]
                             + 4 * drive[3] + drive[4])  # step 0.5, from 0 to 2
        energies[(n, tag)], drives[(n, tag)] = E, drive
        change = E[-1] - E[0]
        simpson_error[(n, tag)] = (abs(simpson - change) / abs(change)
                                   if change != 0.0 else abs(simpson))
```

For each of the 15 series: the energies $E = \int \rho$ at the five slices; the rates $dE/da_{4,0} = -3(\int p_3 - \int p_t)$ of Section 17.16; and **Simpson's rule** for the integral of the rate from $a_{4,0} = 0$ to 2. On one pair of steps of width h, Simpson's rule is $\int_a^{a+2h} f \approx \frac{h}{3}[f(a) + 4f(a+h) + f(a+2h)]$ (the exact integral of the parabola through the three points; its error falls like h^4). With $h = 0.5$ on $[0, 1]$ and on $[1, 2]$ and the two added, the middle value $f(1)$ appears twice: $\frac{0.5}{3}[f_0 + 4f_1 + 2f_2 + 4f_3 + f_4]$. The results are stored under the key `(n, tag)` (a tuple can be a key of a dictionary). The relative error compares Simpson's integral with the recorded change $E(2) - E(0)$; when the change is zero (the $N = 8$ series) the absolute value is stored instead.

```
moving = [key for key in simpson_error if key[0] != 8]
largest = max(simpson_error[key] for key in moving)
unchanged = all(np.all(energies[(8, tag)] == energies[(8, tag)][0])
                and np.all(drives[(8, tag)] == 0.0) for tag in TAGS)
```

The ten series with $N = 136$ or 688 move; `largest` is their largest relative error. `unchanged` confirms that every $N = 8$ series has the same energy at every slice and zero rate (their $p_3 = p_t$, Notebook 17a, In [18]).

```
for n in (136, 688):
    E, error = energies[(n, "lam0")], simpson_error[(n, "lam0")]
    say(f"N = {n}, lambda = 0: E(0) = {E[0]:.6g}, E(2) = {E[-1]:.6g}, "
        f"change {E[-1] - E[0]:.6g}, relative Simpson error {error:.1e}")
report("largest relative Simpson error, N = 136 and 688", f"{largest:.1e}")
reproduces(no_crossing and largest < 1e-3 and unchanged,
           "E(2) - E(0) = integral of -3 (int p3 - int p_t) along the history",
           KS_RUST, ["emt_energy_change_dE_da4"])
```

Output: for $N = 136$, $\lambda = 0$: $E(0) = 80.2822$, $E(2) = 12.4451$, change -67.8372, relative Simpson error 2.1×10^{-4}; for $N = 688$: 680.441, 110.387, -570.055, 2.2×10^{-4}; the largest relative error of the ten moving series, 2.2×10^{-4}; and the PASS line, which also requires the solver's check `emt_energy_change_dE_da4` (the same law with tiny steps of a_4) to be PASS. (COMPUTED. The remaining error is that of Simpson's rule with only five slices, not of the law: the solver checks the law with steps of 0.002 in a_4 to 1.5×10^{-10}, measured as in Section 17.16.)

In [19], the energy along the history (figure 5).

```
fig, (left, right) = plt.subplots(1, 2, figsize=(9.6, 4.0))
slice_values = np.array(list(SLICES.values()))
for n, marker in ((136, "o"), (688, "s")):
    E, drive = energies[(n, "lam0")], drives[(n, "lam0")]
    to_one = E[0] + 0.5 / 3 * (drive[0] + 4 * drive[1] + drive[2])  # 0 to 1
```

```
    to_two = to_one + 0.5 / 3 * (drive[2] + 4 * drive[3] + drive[4])  # 1 to 2
    left.plot(slice_values, E / E[0], marker=marker, color=N_COLOURS[n], lw=1.6,
              label=f"$N = {n}$: recorded $E$")
    left.plot([1.0, 2.0], [to_one / E[0], to_two / E[0]], "x", color="black",
              ms=9, mew=1.6)
```

For $N = 136$ (circles) and $N = 688$ (squares) with $\lambda = 0$, the left panel draws $E/E(0)$ at the five slices, and black crosses (`"x"`, with marker edge width `mew`) at the energies predicted from $E(0)$ by one Simpson step to $a_{4,0} = 1$ and a second to $a_{4,0} = 2$.

```
left.plot([], [], "x", color="black", label="from $E(0)$ by Simpson")
left.axhline(1.0, color="#e34948", ls="--", lw=1.2, label="C3: constant energy")
left.set_xlabel("slice $a_{4,0}$ (history $a_4 = Hx_4$)")
left.set_ylabel("$E(a_{4,0}) / E(0)$")
left.set_ylim(0.0, 1.1)
left.legend(fontsize=7, loc="lower left")
```

A legend entry for the crosses (an empty plot, as in Notebook 17a, In [15]), the red dashed line of the constant energy that C3 needs, labels, the vertical range and the legend.

```
keys = [(n, tag) for n in (136, 688) for tag in TAGS]
labels = [f"{n}, {tag[3:]}" for n, tag in keys]  # N and the coupling tag
right.bar(range(len(keys)), [simpson_error[key] * 1e4 for key in keys],
          color=[N_COLOURS[n] for n, _ in keys])
right.set_xticks(range(len(keys)), labels, rotation=60, fontsize=7)
right.set_xlabel("series ($N$, coupling: m2 $= -\\lambda_2$, ..., p2 $= +\\lambda_2$)")
right.set_ylabel("relative Simpson error ($10^{-4}$)")
fig.tight_layout()
```

The right panel draws one bar per moving series: its relative Simpson error times 10^4, coloured by N; the bars are labelled with N and the coupling tag (`tag[3:]` drops `lam`), turned by 60 degrees.

```
fall = [energies[(n, "lam0")][0] / energies[(n, "lam0")][-1] for n in (136, 688)]
```

`fall` is the factor by which the energy falls from the first to the last slice, for $N = 136$ and $N = 688$.

```
